On October 25th, my father first saw the patient; at this time she was having a chill every day or every other day, with a temperature from 100° to 101° F. The next week I saw her; she was then in a deplorable condition, her entire trouble was referred by herself to the difficulty in getting a passage, which she dreaded on account of the pain, which she described as "something terrible, forcing her to bear down as if she were 'going to have a baby.'" A movement was only secured by the repeated administration of large doses of powerful cathartics, and was accompanied by a distressing, burning sensation in the rectum which could not be relieved. The anus, she said, would at these times "draw up toward the inside," while the passage was "very small, like a baby's." Her other symptoms were accompanied by a persistent anorexia and daily vomiting, that threatened a speedy termination unless relief should be obtained.

A rectal examination revealed, at three and a half inches, a firm annular stricture, so small and resisting that the examining finger could not be made to engage in it. On making a vaginal examination the cervix was free, that is, as free as is possible with a fixed fundus. The fundus was retroflected, drawn to the left, and firmly fixed to the sacrum. Passing from the fundus laterally could be felt on either side a firm band, not sensitive to pressure, shorter and thicker on the left than on the right side. These bands occupied the site of the superior border of the broad ligament, passing off from either side of the uterus at its fundus, but did not extend throughout the width of the broad ligaments down to the cervix. Ovaries and tubes not to be differentiated.

On November 15th, assisted by the house staff at Charity Hospital, in the presence of Drs. W. J. Scott, Weber, and Lucas, I opened the abdomen by a four-inch incision, with the expectation of at least partially relieving the rectum by freeing the uterus, lifting it up, and doing a ventro-fixation. The uterus was retroflected, drawn to the left, and fixed to the sacrum; so firm were the adhesions, and to such an extent had the cicatricial contraction taken place, that the peritoneum of the fundus had a white, glistening, bloodless appearance. The left tube and ovary were not found, but their site was occupied by a mass of new connective tissue. The rectum skirted along the promontory of the sacrum just above the fundus of the uterus, and dipped down into the pelvis to the right of that organ, instead of the left where it is usually found. Commencing above to free the rectum, the vermiform appendix was found adherent to its anterior surface; this was freed, and being normal, was put over into its proper place. The tube and ovary, containing a small cyst which ruptured during the manipulations, were next lifted from the rectum. Very little ovarian tissue was left, the most of it being substituted by cicatricial tissue. The right broad and the round ligaments were found to be much shortened, these, reinforced by the inflammatory new connective tissue between the rectum and broad ligament, formed a firm stricture of the rectum. The broad ligament, including the round ligament, was cut between forceps well down into "Douglas's pouch," and the anterior and posterior layer of peritoneum stitched together on either side of the cut. After stopping the oozing, and flushing the abdomen, the external incision was closed with silkworm gut. A rectal examination showed that the stricture had been immediately relieved.

I have prepared some diagrams to illustrate the condition at the time of operation.

Fig. 1, after Savage, I have modified to represent a transverse section of the body, showing the normal position of the fundus uteri, situated at about the centre of the pelvic cavity, with the broad ligament and the structures contained therein: the ovary, tube, and round ligament passing out laterally to the pelvic walls.

Fig. 2 represents a transverse section of the body, showing the site of the inflammatory exudate and adhesions. This chart is largely hypothetical; as there was no vaginal examination for several months after the confinement, there is no way of knowing how much of an exudate there was during the earlier stages.

Fig. 3 represents a transverse section of the body,

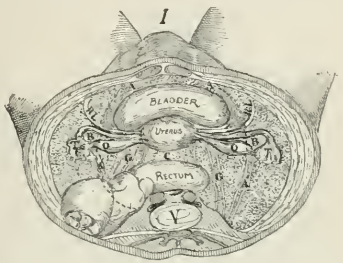

Fig. 1.—Transverse Section of the Body, Showing Normal Position of Fundus Uteri: *A*, hypogastric artery; A^1, spermatic vessel and nerve; *B*, broad ligament; *C*, sacro-uterine ligament; *G*, ureter; *O*, ovary; *T*, tube; *RL*, round ligament; *V*, last lumbar vertebra; dotted line indicates the true pelvis. (Modified from Savage.)

showing the relation of the pelvic viscera, in the case under discussion, at the time of operation. The rectum passes down into the pelvis on the right side, the uterus is drawn to the left, and fixed. To the left of the uterus is the short band of connective tissue enclosing the remains of the ovary, tube, and broad ligament. To the right of the uterus the broad ligament, passing from the

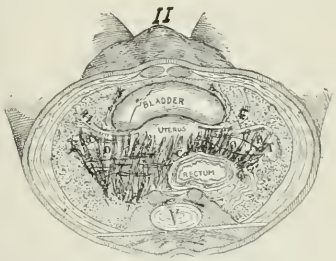

Fig. 2 (hypothetical).—Transverse Section of the Body, Showing the Site of the Inflammatory Exudate. (References as in Fig. 1.)

fixed uterus on the one hand to the pelvic wall on the other, shortened and reinforced by the inflammatory new connective tissue, forms a firm band, pressing down upon the rectum, and preventing that organ from performing its natural functions. *V* represents the site of the operation.

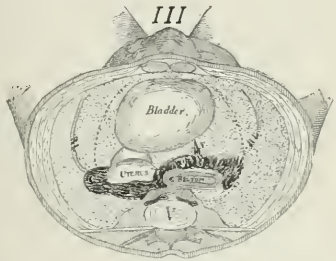

Fig. 3.—Transverse Section of the Body, Showing the Relations of the Pelvic viscera in the Case of Rectal Stricture of Mrs. M.: *RL*, round ligament; *C*, cicatricial mass including the left tube and ovary; *O*, right ovary, adherent to rectum, covered by new connective tissue; *V*, site of operation.

Convalescence was uneventful. One month after the operation I have in my notes the following: "Feels perfectly well. Cannot get enough to eat, but suffers no discomfort from eating. As soon as her head touches the pillow she is asleep; first restful sleep since last April. Bowels move every day, and has taken cathartic but once

since coming home." To-day, six months after the operation, she says her health is better than ever before. Surely not the ordinary result of an operation for stricture of the rectum by the old methods!

The literature of the subject contains numerous cases of obstruction of the intestinal tract by bands of various kinds: some of them extending to the true pelvis, or even located in it; but the following three cases only may be fairly called false stricture of the rectum, although not so reported.

In 1854–55,[1] Mr. T. J. Ashton exhibited to the London Pathological Society a specimen showing "Stricture of the rectum, from a deposit of fibrous tissue external to its coats."

"F——, aged fifty-four, admitted to hospital with a history of disease of the rectum of twenty years' standing; examination showed a contraction of the bowel to exist at three inches from the anus, surrounded by a dense mass of morbid structure. On post-mortem examination, the intestines were found greatly distended. No peritoneal inflammation existed. The rectum was contracted at the part already mentioned, and was surrounded by a large mass, having the appearance of fat, and very dense; but by the aid of the microscope, as well as subjecting the specimen to the action of ether, it was found to be composed of fibrous tissue alone."

January 11, 1893,[2] Dr. Biggs exhibited to the New York Pathological Society a specimen of which he says: "It was removed from a woman, thirty-five years of age. There were extensive adhesions from the upper border of the uterus directly backward to the rectum. It was interesting to note that the origin of the trouble was tubal. A firm band of fibrous tissue, nearly half an inch thick, surrounded the middle portion of the rectum, causing so much obstruction that it was with difficulty that the little finger could be forced through the opening. Above this point there was very marked dilatation of the gut, and in the sigmoid flexure and ascending colon there was very extensive diphtheritic inflammation."

Dr. Edwards[3] also reports a case found at post-mortem, in which "The cause of all the trouble was a cartilaginous band, about one and a half or two inches wide, which had gradually occluded the gut completely from seven and a half to nine inches above the anus."

It is probable that most false strictures are due to an inflammatory process starting without the rectum. Dr. Biggs's case was apparently of that character, and my own was undoubtedly the result of such an inflammation.

That the latter was of puerperal origin there can be no doubt, as the history is clear on this point. None of the older authors mention the puerperal condition as an etiological factor of stricture of the rectum. Whitehead, even as late as 1888, in a lengthy address on stricture of the rectum, says: "I have no knowledge whatever of child-bearing as a cause of rectal stricture." The modern authors are, however, beginning to recognize it as an etiological factor. Wyeth's and Moullin's Surgeries contain the simple assertion that the "accidents of parturition not infrequently tend to stricture."

The differential diagnosis between true and false stricture is most difficult, since there is no pathognomonic sign or symptom. The clinical history of both are alike; a rectal examination reveals apparently the same condition. But if on vaginal examination, or otherwise, a pelvic band can be felt, especially if the uterus is fixed posteriorly, the stricture may be suspected as a false stricture. May it not be that quite a proportion of those found in women are false strictures?

Let us review for a moment the methods of treatment advocated for stricture of the rectum. They are, combined with constitutional treatment, the bougie, linear proctotomy, and colotomy.

The use of the bougie is not without danger, and even after the stricture has been fully dilated, the instrument must be passed at intervals to prevent its recontraction. Surely not a cure!

Of linear proctotomy "The American Text-book of Surgery" says: "It cannot be practised when the stricture is high up or of great extent; here we must perform colotomy to save the patient's life." The four cases forming the basis of this paper were from three to seven and a half inches from the anus, and it is not improbable that most false strictures are high up, situated above the floor of "Douglas's pouch." Any operation through the rectum must not only cut through sound tissues, exposing them to the dangers of infection, but, if the operation is thorough enough to divide the constricting band, must also open the peritoneal cavity, which is the danger to be feared in linear proctotomy.

Colotomy is rightly a last resort; and, if a case judged to be a false stricture proves, on opening the abdomen, not to be directly amenable to surgical treatment, a colotomy can be performed, and the median abdominal incision closed, without materially adding to the dangers of the colotomy.

I have endeavored to show that there are cases of stricture where the pathological condition is situated outside of the rectum. These I have denominated false stricture in contradistinction to true stricture.

False stricture is usually the result of an inflammation starting without the rectum.

The puerperal condition is an important etiological factor.

Presents the same clinical picture as the true stricture.

Situated above the floor of "Douglas's pouch."

Theoretically, false stricture can be best treated by laparotomy.

OXYGEN IN CHOLERA CURSORILY CONSIDERED.

By R. HARCOURT, M.D.,

ASSISTANT SURGEON TO THE DEMILT DISPENSARY, NEW YORK, AND DISTRICT PHYSICIAN TO THE NEW YORK LYING-IN-ASYLUM, ETC.

THE enunciation made by Mayo about two hundred years ago, "that there is something in the air absolutely necessary to life which is conveyed into the blood," excepting that the "something" was not named, expresses what is now regarded as one of the great objects of respiration.

The "something" already referred to is, of course, oxygen. Discovered almost simultaneously in 1774 by Scheele and Priestley, published under the names empyreal and dephlogisticated air, it was left for Lavoisier to give it the present designation of oxygen. Raoul Pictet, of Geneva, first reduced it to a liquid state, by cold and intense pressure; as a gas it is colorless, tasteless, heavier than atmospheric air, and the sustaining principle of animal life and all ordinary phenomena of combustion.

Man's function is to fill a certain niche in the gallery of the world; and be this ever so humble, he who fills it in a thorough and conscientious manner will best benefit himself and the world; to do this activity is necessary, bearing in mind, although the term may sound paradoxical, there is such a condition as active quiescence. Activity means health, to be healthy it is essential that we consume, with other things, a proper and pure supply of oxygen.

To a scientific investigator the modern beliefs expressed regarding oxygen in its varied aspects, are worthy of some special concentration of mental activity. So much has been written and so many views have been advanced regarding this gas, that a paper at this time must necessarily be to some extent a recapitulation of facts already stated; but to a real scientist, using this term in contradistinction to the term "scientific quack," a recapitulation on this subject will no doubt be somewhat interesting. Wild theories and ludicrous statements, the authors of which being well-meaning and often remarkably clever men, will have to be taken *cum grano salis*, swallowed in the proper manner (so to speak), when, if acted upon by the mental gastric juice (provided it be of the proper

quantity and quality), will be assimilated at their true worth, going to provide nutriment for the structure of the intellect; by nutriment is meant knowledge of indisputable and incontrovertible facts. It is much better for nothing to be written than to have an accumulation of graphic mistakes.

Speaking of warm-blooded animals, the statement may be made that without oxygen there is no life, and that said animals consume in a certain way or manner a graded quantity of the gas. It is quite rational to accept this statement, that this is increased or decreased during abnormal physical conditions which may be present. When writing of oxygen as a remedy, prophylactic or otherwise, it is of course of primary importance to consider it relatively with man.

Atmospheric air in passing through the lungs increases in temperature, due to contact with tissues, and also gains watery vapor, ammonia, and a small quantity of organic matter. The volume of oxygen consumed is about five per cent. of this entire volume of air. The quantity of CO_2 exhaled is four per cent. of the entire volume of air, showing a certain quantity of oxygen lost in the lungs, a part of which is found to participate in production of animal heat, and some uniting with hydrogen to form water.

Oxygen in Cholera.—The various ways and means by which we are instructed to treat cholera are multiform: Simple and difficult, practical and impracticable, partly successful and unsuccessful; but the fact that good results are, comparatively speaking, not often attained, indicates that we ought and do appreciate any suggestion which will tend to alleviate the suffering and misery of the patient, and to attain success in treatment. The wide divergence of opinion on both the subjects of etiology and the treatment is due to a great extent, it must be remembered, to the difference in the character of various epidemics, in individual cases, and in the climatological situation and sanitary aspects co-existing.

It would be well to remember that there is no direct relation between the degree of collapse and amount of discharge: indeed, in the most fatal cases the discharges are slight or absent. The occurrence of collapse is the point against which we are to lead our remedial forces: in regard to the causes of the symptoms of which the conclusion is reached by a very able observer, that they are produced by obstruction of the circulatory fluid in its passage through the lungs. Post-mortem examinations show that in cases in which death occurred during the stage of collapse, the right aorta, the pulmonary artery, and the great systemic veins were obstructed with blood, while the left aorta was found to be nearly empty. Blood containing the virus excites the arterioles to contract, the supply of oxygen is diminished in proportion to the defective current of arterial blood, the circulating blood and the tissue both become deoxygenated, the elimination of CO_2 is diminished, and there is almost complete suppression of bile and urine. That these symptoms are due to defective oxygenation is proved by the fact that, in the case of a nursing mother becoming infected with the disease and falling into collapse, the secretion of milk continues unchecked, the breasts even becoming painfully distended. The chief ingredients of the milk, viz., sugar, fat, curd, and water, unlike bile and urine, can be obtained from deoxygenated blood.

When it is considered that the soft tissues of the body contain four-fifths of all the water in the organism, it will be readily seen that the extraction of watery constituents from the blood will not cause it to become thickened, as it can draw on the reservoir of water in the tissues, thus maintaining liquidity by compensation, the tissues diminishing in proportion to amount of water given up, which process takes place with great rapidity. If the body can be kept warm by any means, the painful cramps of the muscles will be relieved, the pulmonary arterial spasms will relax by heat of returning venous blood, and the pulse will be of a good character. The statement that Dr. Cuneo saved six patients affected with cholera by forcing oxygen into their lungs, shapes out a line of thought regarding this remedy as herein applied. As before stated, in this disease the symptoms of collapse are produced by obstruction of pulmonary circulation, which condition will bring about deficient oxygenation of both blood and tissues. Now, as it is of primary importance that we maintain normal animal heat, for which the necessity of oxidation of the tissues is well known (by oxidation is meant the application of the chemical law, that is, when a body is burning it enters into union with the oxygen), all tissues, as long as they retain their absolute integrity of composition, can appropriate oxygen and exhale CO_2. The blood being the only channel by which the tissues can be supplied with the gas, every means possible should be made use of to cause it to be taken up by the blood. The physiological law which says that blood will only appropriate a certain quantity of oxygen, has to be carefully considered, but it will be remembered that in cholera an abnormal condition is present, namely, obstruction of the pulmonary circulation, in which condition it is said one lung often does duty for the two, by way of the blood it contains taking up a nearly double quantity of oxygen, clearly proving that in cholera the judicious use of oxygen would be one the best resources which can be commanded; first, constitutionally as a tonic, and secondly, by assisting nature in her conservatism by keeping up normal oxidation until she has thrust out the poison by way of frequent diarrhœic discharges.

Probably the diseases in which oxygen has been of greatest value are pneumonitis and septicæmia, and there is not wanting literature testifying to the remarkable results obtained from the use of the gas in these abnormal conditions.

Clinical Department.

METHYLENE BLUE AS A REMEDY AGAINST DIPHTHERIA.

By A. ROSE, M.D.,

NEW YORK.

DURING the last few weeks I have been employing, locally as well as internally, methylene blue in different forms of diphtheria, and also in non-diphtheritic ulcerations of the throat, invariably with surprisingly good results. I was induced to apply this drug, with which I had had, like many others, quite extensive experience in the treatment of malaria, by an article of Dr. A. Kasem-Beck, which appeared in the *Centralblatt für klinische Medicin*, June 24, 1893, entitled: "On the Treatment of Malaria by means of Methylene Blue and the Local Application of this Drug in Diphtheria."

Dr. Kasem-Beck reports his good results in different forms of diphtheria, most of them associated with swelling of the submaxillary lymphatic glands. He applied an aqueous solution (1–9) two or three times daily to the ulcerated membranes.

Dr. Beyer had already reported in 1891 (*Allgemeine Centralzeitung*) on fifty cases of diphtheria pharyngis successfully treated by internal administration of methylene blue mixed with powdered sugar.

On July 1st I was called to attend upon a boy, ten years of age, with diphtheria of nose and throat, high fever, considerable swelling of submaxillary lymphatic glands. The treatment consisted principally in administration of solution of bichloride of mercury internally, hydrate of chloral to the throat, and lime-water to the naso-pharyngeal space, locally. It was of no avail. The child died. The disease had probably been contracted in the next-door house, where a child shortly before had died of diphtheria. Two other children in my patient's family also took sick with diphtheria on the same day my first patient died. Both these new cases commenced with extensive ulceration of the throat: in one of them the nasal membrane was also affected. Both soon had

swelling of the submaxillary lymphatic glands and high fever.

On the very day these new cases happened I had received by mail the above-mentioned article of Dr. Kasem-Beck, and I was so favorably impressed with it that I at once resorted to the methylene treatment. I applied the solution to the affected membrane of the throat every two hours; to the nose, in the one case, three times a day. The result was most gratifying. Both made a quick recovery.

I attended since a case of diphtheria of the nose, throat, and larynx, with swelling of the submaxillary lymphatic glands and high fever, in a child two years of age. In this case I gave methylene blue locally as well as internally, the latter form of administration in the shape of lozenges sweetened with saccharin, containing one centigramme of the drug. The result was excellent. Recovery within one week.

In simple non-diphtheritic ulceration of the throat, patients would, after one or two applications of the solution, express themselves with great delight as being cured.

In all cases of exclusively topical treatment the urine became blue. I agree with Dr. Kasem-Beck, who thinks that the methylene blue entering the general circulation has an influence on the course of the diphtheria.

When I asked Messrs. Eimer & Amend to suggest to me a convenient form to give the very disagreeable methylene blue internally to children, they informed me that they had been for some time making methylene lozenges for a physician residing on Staten Island, who ordered them in cases of diphtheria to be dissolved in the mouth, thus securing at the same time topical and internal application. The lozenges which were made for my patients dissolved readily in the mouth, and were, on account of being sweetened with saccharin, not unpleasant to take.

Judging from theoretical reasons, I shall try these methylen lozenges in cases of whooping-cough, when opportunity shall present itself.

It has happened to me that methylene violet instead of methylene blue had been dispensed to my patients. I learn also that similar mistakes have occurred elsewhere.

215 Second Avenue, August 6, 1893.

DEAFNESS FROM MUMPS.

By HAL FOSTER, A.B., M.D.,

KANSAS CITY, MO.

LARYNGOLOGIST TO ALL SAINTS' AND MISSOURI PACIFIC HOSPITALS.

When I was a medical student in the office of Dr. McLaury, of New York City, I remember his saying to a lady patient, after she had asked him if there was any danger, "Yes, there is danger in all sickness, no matter how slight the ailment." I have seen those remarks confirmed many times. The case I wish to report comes under that heading. Mumps is considered both by physicians and patients as perfectly harmless. Fortunately, in the great majority of cases this is the rule.

Occasionally dangerous and disastrous sequelæ are met with. The history of my case is one of more than usual interest.

Its comparatively rare occurrence, the difficulty of diagnosis, and the sudden speedy termination entitle it to be noticed. On the morning of May 5, 1893, Mr. and Mrs. H. G. F—— were sent to me from Council Grove, requesting me to examine their son. The patient was a bright-looking boy of four years. There was no specific or tubercular disease in the family. The parents were well and had always been so. The other children in the family were well and strong. This boy had escaped all the infantile diseases, such as scarlet fever, etc. In fact, his mother informed me he had never been sick a day in his life. Two weeks ago he was sitting in his father's back yard, on the last door-step (which was only eight inches from the ground) in company with several children. Suddenly, without warning, he fell, striking the head against the board sidewalk, which dazed him for a few moments only.

His father came home several hours afterward; his son met him at the front gate and told him all about the fall. The boy retired at the usual hour that night, and no unusual symptoms were noticed until his mother attempted to dress him the next morning. He was then unable to stand, was dizzy, vomited, and told his mother that bugs were singing in his ears.

She called the family physician, who examined him and advised her to keep the patient in bed that day, without any medicine. On the morning of the following day the boy appeared to be perfectly well, with the exception of being absolutely deaf. He would look at his mother and say, "Mother, why don't you talk to me?" She talked to him all the time with no results. He had been in this condition for two weeks when I saw him. I examined him very carefully and found him to be in a splendid condition. His throat and nose were normal, he placed his hand to his ear and said, "Hear that noise." Immense quantities of dry wax were washed out of each ear.

The drums could now be seen, and with the exception of a little redness they were normal. At this time I thought that the trouble was due to the wax, and was in hopes that he would be able to hear by the next day's treatment. On entering my consultation-room the next morning the father said, "Doctor, this boy is still as deaf as a post." The tuning-fork and watch tests were now used with negative results. To all of my tests he gave no evidence of hearing anything.

Thinking that a neurologist could locate the trouble, I called my friend, Dr. John Punton, who examined the patient, and said that the nervous system was not injured in any way. I then asked Dr. J. H. Thompson to examine the boy. He pronounced the ear-drums in good condition. The mother said at this moment, "Doctor, I forgot to tell you my boy had the mumps when he fell; both sides were involved so very slightly that he was never in bed." The diagnosis of deafness from mumps was then at once made. He was now placed on large doses of iodide of potash in liquid pepsin, mercury by inunction, and pilocarpine in small doses by subcutaneous injection. The ears were inflated, and the above treatment continued for two weeks.

The pilocarpine had to be now discontinued and fluid extract of jaborandi substituted; with this exception the same treatment was continued for a month. The boy's general health seemed to improve greatly, but he remained as deaf as ever. I told the father I could do nothing for the boy, and explained to him the grave condition the ears were in, and advised sending his son to the school in Olathe for deaf children.

Pomroy reports several cases of this kind, and says the peculiar poison which causes the disease is very often the source of complete deafness. Roosa says the deafness comes on suddenly, is usually complete, no appearances of disease can be detected in any part of the ear. Toynbee reports some cases, and says he was unable to detect anything abnormal about the tympanic cavity. Dr. Knapp also reports several cases.

Dr. J. H. Thompson informs me that he has seen several cases, without any trace of disease of the middle or external ear. Schwartze (page 439) reports a number of cases. Dr. Burnett [1] says, "A peculiar metastasis may occur by which the labyrinth becomes affected and total deafness results."

The above-named seem to agree as to the cause, and the grave prognosis in these cases. The hearing is seldom if ever restored. As far as I have been able to find, treatment has not cured or benefited a single case. In my case the metastasis took place, and the labyrinth became affected, while the boy was sitting on the steps, causing him to fall; at least this is my opinion.

[1] System of Ear and Throat Diseases, p. 528.

PYREXIA IN ACUTE ANÆMIA.

By A. REICH, M.D.,
NEW YORK.

Mrs. S——, aged forty, IV.-para, was confined June 14, 1893. Presentation, vertex, position, L. O. P.; the first and second stages of labor lasted eight hours; the occiput did not rotate and was born in that position. The third stage did not come on for twenty-five minutes. I wanted to resort to Credé's method; to my surprise the uterus was flabby, distended; a large amount of blood covered the bed and she was still flooding slowly. Ergot by the mouth and manipulation of the uterus through the abdominal walls soon caused it to contract. The temperature now, at 2 A.M., was 97° F.; pulse very soft. At 10 A.M., temperature, 100° F.; in the evening, 102° F., and it fluctuated between 100° and 102½° F. for five days, but became normal at the end of the week. During this time the lochial discharge was normal and the patient felt comfortable.

Progress of Medical Science.

The Pathology of Laziness. — Many persons are unjustly compelled to bear the reproach of laziness, when their indisposition to exertion really has a physical basis, and depends upon some grave disturbance of nutrition. Such cases deserve our sympathy, instead of the contempt which is unsparingly meted out to them by their more robust associates. Women, whose instincts are often remarkably correct, understand this, and when a child is unusually quiet and prefers to sit still, instead of joining its companions in play, the mother's fears are aroused; she thinks at once that something is wrong, and that the child is going to be sick, or is actually suffering from some obscure internal disorder, possibly hip-joint or spinal disease. This explanation may apply in adults as well as in children. Some years ago, a clergyman, who had been very active in church work, was noticed to gradually give up one duty after another, and to show marked disinclination to perform any work requiring much exertion of body or mind. He was generally thought to be losing his interest and getting indolent. Indeed, he feared himself that this was the case, and it gave him much mental distress and spiritual disquietude. He afterward came under the observation of a physician, who found that he was a sufferer from Bright's disease, from which he subsequently died. He was especially regretted by those who had hastily and ignorantly condemned him for what was assumed to be a fault, but which, in reality, was due to grave disturbance of nutrition from the approaches of an insidious organic disease. Victims of chronic malarial poisoning afford typical illustrations of laziness, although clearly suffering with bodily disorder. Who can estimate the amount of physical disability and apparent indolence which is directly due to dyspepsia and chronic indigestion? Rheumatism and the muscular pains of lithæmia, locomotor ataxia, and its nerve-counterfeits, incipient brain disease, and arterial degeneration, are all potent factors in producing indolent habits of body, while phthisis, pernicious anæmia, and neurasthenia have physical weakness as a prominent and early symptom. A dislike for study in a child may often be traced to errors of refraction which are remediable by properly adjusted lenses.

Before pronouncing, therefore, a verdict of moral fault, and condemning those who are conspicuously deficient in energy, and whose powers of work are notably below the average, it would be well to stop and inquire whether they are not laboring under physical disability instead of indolence. In such cases it may be found that better results will be obtained by placing them under the charge of a physician than under an instructor in morals. The decision between the hospital and the work-house is often a difficult one to make for those wrecks of humanity, the physical degenerates, who become tramps because they have a moral and physical aversion to work. In a strictly analogous manner, in higher walks of life, when a physician prescribes physical exercise for patients who obviously require it, he often finds his instructions disobeyed simply because the physical disability of the patient is the real reason for his condition; for if he had the power to follow the prescription he would not need the advice. It appears, indeed, that, in certain instances, laziness may be a conservative effort of nature; and, as a symptom, will be estimated at its proper value by the intelligent physician.—*Food.*

Three Infectious Diseases Incubative at the Same Time.—Dr. J. T. C. Nash writes to the *British Medical Journal* that he recently had under his care a child of three and one-half years, in whom were developed within a week the following infectious diseases in the order named: whooping-cough, chicken-pox, measles. The incubative period of pertussis is stated to be a few days, that of chicken-pox to be variable, and that of measles from seven to ten days, and the point of interest, the writer holds, is that three distinct poisons should flourish in one *corpus vile*, and come to full maturity at one and the same time.

Illumination of the Eyes from Behind.—When an incandescent lamp is introduced into the mouth, for the purpose of ascertaining, by trans-illumination, the condition of the maxillary antra, the pupils are seen as blood-red apertures. Mr. N. Stevenson calls attention to the curious fact that when the light is thus introduced, as it were, by a back door, the pupils do not contract. This observation may prove to possess considerable importance.—*The Medical Press.*

Congenital Absence of Nails.—Dr. Hermann Eichhorst reports in the *Centralblatt für Klinische Medicin* of April 8, 1893, the case of a man, twenty-six years of age, who had no nails on either fingers or toes. The nail-bed and fold were well formed, and the former presented a shiny surface, giving the appearance of a very thin nail. Close examination showed, however, that there was not the slightest trace of a nail, the skin of this part being softer and more delicate even than the surrounding integument. Sensation was also as acute here as on the palmar surface of the fingers. The man's hair and teeth were perfectly normal.

The Bacteria of the Stomach.—In the *Journal of Pathology and Bacteriology*, Dr. Gillespie has published the results of his observations on the micro-organisms which he found in the gastric contents of various patients. Twenty-four varieties of microbes were obtained. They were cultivated on various media to ascertain their products, especially with regard to their acid-producing power, and to estimate the effect of hydrochloric acid added to them. The organisms obtained were largely those of well-known species. The conclusions deduced from the author's studies are as follows: 1. Many organisms can grow in the human stomach. 2. Many of them can be grown from the contents of the stomach even when they are very acid. 3. From many cases in which organic acids are present in the stomach contents, micro-organisms can be grown which produce the same acid on suitable media. 4. Most of the organisms so grown are very resistant to the action of acids. 5. Hydrochloric acid combined with proteids has little inhibitory power on organisms, in comparison with free hydrochloric acid. 6. More micro-organisms can be grown from the gastric contents if plates are used and a medium that will not liquefy at the body temperature, than if plates of gelatine be used. Agar-agar is a good vehicle. Yeasts and mucoids, however, are best grown in bouillon, being isolated afterward on gelatine plates. 7. Micro-organisms, if present in quantity, exercise a deleterious effect on both gastric and pancreatic digestion. 8. Pathogenic organisms, which are usually very markedly affected by hydrochloric acid, may pass through the stomach unharmed if the meal with which they are ingested be large and chiefly

proteid in character; provided also, it may be from some fortuitous circumstances, that the supply of hydrochloric acid be somewhat deficient. Under these circumstances most, if not all, the secreted acid combines with the contained proteids. 9. Many non-pathogenic germs do, as a matter of course, pass through the stomach unharmed or only temporarily inhibited. This accords with Macfadyen's observation that the bacteria of the small intestine are constantly changing in numbers and varieties. 10. A small quantity of the free acid, if combined acid be also present, is sufficient to kill or inhibit organisms which could resist a similar quantity of the free acid alone. 11. Although bacteria are of no aid to peptic digestion, and are a hindrance to the pancreatic ferment if in quantity in the duodenum, they still are of great use in the small intestine, where they control putrefaction. The organisms which most easily pass the stomach are those which give rise by their growth to the fatty acids, as they are most resistant to the action of the acids. Their products in the small intestine are sufficient to keep the contents of that viscus acid, and they thereby prevent or control putrefaction. In the large intestine the secretion is so alkaline that the putrefactive organisms reassert themselves. 12. Increased putrefaction in the intestinal canal may therefore be due, in some cases, either to insufficient mortality among the putrefactive organisms in the stomach, or to too great mortality among the acid-forming bacteria and yeasts. 13. The lactic acid which appears during the first stages of digestion is due to the action of organisms. 14. The lactic, acetic, butyric, and succinic acids found in gastroectasis are due also to organisms which luxuriate in the too stationary contents.

The Medical Profession in France.—In a report presented to the French Senate by Professor Cornil, some interesting statistics are given respecting the number and distribution of medical practitioners in France between 1847 and 1891. In the former year there were in the whole of France 17,400 practitioners, of whom 10,268 were Doctors of Medicine and 7,233 *officiers de santé*. In 1891 the total number of practitioners had fallen to 15,046, the decrease, however, being confined to the class of *officiers de santé;* the number of Doctors of Medicine had risen to 12,553. The proportion of the latter to population varied from 1 to 1,287 in the Seine department to 1 to 7,669 in the Haute-Loire department, the average being 1 to 3,000. The proportion of *officiers de santé* to population, on the other hand, averaged 1 to 17,000.

Functional Diarrhœa.—Dr. Stein points out the importance which has hitherto been attributed to catarrhal and inflammatory conditions of the intestine in producing diarrhœa. (*The British Medical Journal.*) In the stomach many disturbances, formerly supposed to depend upon a catarrhal condition of its mucous membrane, have now been found to rest on a functional basis, which is natural in view of Ewald's remark that the stomach does not really possess a mucous membrane. Analogy has led the author to a similar conclusion regarding the intestine, and he quotes, in support, the experiments and researches of Moreau and Rindfleisch, as also the statement of Cohnheim, that in patients who die of cholera the intestinal mucous membrane is not found to be in an inflammatory condition, but only injected and vascular as during digestion, and that the "rice water" is only abundant normal secretion. Similarly, Cohnheim does not admit that infantile diarrhœa is always accompanied by inflammation; and these and other circumstances lead the author to recognize the frequency of a purely functional diarrhœa, attended by increased peristalsis, diminished absorption, and eventual increase of secretion, but without the presence of pus or blood in the stools. The diagnosis of this condition rests with the history and the exclusion of all circumstances which could lead to a catarrhal or inflammatory process. With regard to treatment, opium only acts by inhibiting peristalsis, and the only drug possessing a direct sedative effect on unstriped muscle is atropine, which paralyzes the nerve-endings and ganglia in the intestinal wall. This the author used successfully, administered as the extract of belladonna three to four times daily, supplemented by creosote or other antiseptic, to obviate the harmful fermentative changes. Great benefit is also derived from the use of galvanic, and especially faradic, currents of 3–10 milliampères, as also from hydro-therapeutic measures and local warmth.

Uræmia Treated by Subcutaneous Injections of Kidney Extract.—Professor Dieulafoy reports a case in which this method was adopted. The patient, a man aged forty-three, presented well-marked uræmic symptoms, with œdema of the lungs and oliguria, which rapidly passed into anuria. Other treatment failing to produce the least effect, a glycerine-saline extract of the cortical portion of the fresh kidneys, first of guinea pigs and then of oxen, was prepared according to the method of Brown-Séquard; and after sterilization by filtering, this liquid was injected hypodermically in doses of 3.5 gm. thrice daily, with temporary benefit. The coma passed off and the kidneys again became active. A relapse occurred, however, after three days of this improved condition, and the patient succumbed.

Akinesia Algera.—Under this term Dr. Möbius describes an affection of the nervous system characterized by extreme pain upon motion, so that the patient is unable to make any movement whatever. The exact pathological condition which is the cause of this symptom is as yet unknown. (*The Lancet.*) It appears only to occur in neurotic individuals, especially those who are in a bad state of health generally and who are unable to fight against the weakness. The pain is sometimes directly associated with motion, but in other instances follows it, and is experienced not only in the parts of the body which have been moved, but also in other parts, and may finally lead to almost complete loss of motive power, so that the patient is practically paralyzed. In addition to this pain, which is the most prominent symptom, other phenomena characteristic of neurasthenia may develop, but hysterical outbursts have not been observed. Möbius considers that this disturbance may be attributed to inherited degeneration of the nervous system; that, as a rule, it follows upon mental strain in patients prone to neurasthenia; and that it must be regarded as a psychical affection. The condition must, however, be considered as more allied to hysteria than to hypochondriasis.

Tolypyrin.—Dr. Guttmann has recorded the results of some trials of tolypyrin, a new pyrazol derivative. The new drug is found to resemble antipyrin closely in its action. Its chemical constitution may be described as antipyrin in which one atom of hydrogen of the phenyl group has been replaced by the methyl group CH_3. Tolypyrin forms colorless crystals, melting at 136° to 137° C. It has a bitter taste, is soluble in ten parts of water, slightly in alcohol, and is almost insoluble in ether. Its effect on the temperature in pyrexia was very marked; one drachm given in hourly fifteen-grain doses lowered the temperature at least 1.5° C., generally 2° C., sometimes as much as 3.5° C. The fall of temperature began in the first hour and reached its maximum in five to six hours, the curve being steep. If the administration was commenced at midday, so as to take advantage of the usual remission after midnight, the temperature remained depressed to a notable extent for from twelve to eighteen hours. The fall in temperature was accompanied by sweating, and there was a corresponding fall in the pulse-rate. Its influence on the temperature of pyrexia appeared to be a little greater than that of antipyrin. The observations on the apyretic action of the new drug were made on 6 cases of typhoid fever, 5 cases of pneumonia, 2 cases of facial erysipelas, scarlatina, and phthisis, and 1 case of septicæmia, otitis media, and gangrene of the scrotum with high fever. In acute rheumatism tolypyrin

produced a similar effect to that observed after antipyrin, one drachm producing an amelioration in the joint swellings and in the pain, lasting from twenty-four to forty-eight hours. In its anodyne properties also it was found to resemble antipyrin; in 10 cases of headache it produced complete relief in 6, no distinct relief in 4; of these 4, antipyrin produced relief in 2. In one case of recent sciatica it had a good effect in relieving pain. Tolypyrin is excreted in the urine.—*Berliner klinische Wochenschrift.*

Changes of Type in Epidemic Diseases.—This was the subject of the Milroy Lectures, delivered in London by Dr. Whitelegge. He summarizes by saying that epidemic prevalence may be brought about either by increased potency of the disease itself or by increased mechanical facilities for diffusion. Epidemics of the latter class, including water epidemics, milk epidemics, and, as a rule, seasonal prevalence, are attended with lowered case mortality, because the conditions under which they occur imply a lessened average susceptibility, therefore a less severe average attack. Underlying all great epidemics there is a change of epidemic type, a change in the quality of the disease itself. There is evidence of a like change on a smaller scale in most, if not all, epidemic diseases, the intensity rising and falling at intervals which are not necessarily uniform for the same disease, and are very different in different diseases. Whether on the larger or smaller scale, the intensification is marked by greater severity of attack, greater power of overcoming comparative insusceptibility, and greater power of epidemic diffusion. While some diseases are capable of rapid or even abrupt changes in intensity, others are not; and this distinction serves to mark off broadly two principal groups: those which are mobile and those which are comparatively constant in type. The first group—that of diseases which are capable of most rapid change in type—includes those which are most nearly allied to saprophytic life, most dependent upon filth conditions; most able to infect soil, water, milk, and lower animals; most liable to relapses, and least protective. Diseases of this class may be highly modified, and some of them may assume and maintain a form so slight that their true character is unrecognized. Under favorable conditions, their intensity may slowly or suddenly increase, giving rise to epidemics of severer type. Among diseases of this class, an epidemic normally begins and ends with the milder forms, the more severe attacks occurring at the time of greatest prevalence. The severity and prevalence rise and fall together. In the second group, among diseases of more fixed character, extreme modification of epidemic type does not occur: but individual attacks may be extremely mild, owing to high resistance. Among such diseases there is evidence of a rise and fall of intensity if the epidemic course be traced for a term of years, perhaps covering several minor epidemics. In these brief outbursts of diseases of more constant type there is little, if any, change of intensity comparable to that of the mobile class; the prevalence being determined and controlled mainly by external conditions, but the type being that of the prevailing phase of a broad cycle.—*The Boston Medical and Surgical Journal.*

An Outbreak of the Gastro-intestinal Form of Influenza.—Dr. Thresh has presented a report on the recent outbreak of diarrhœal disease at Ford End, in the neighborhood of Great Waltham, in England. By personal examination he ascertained that the outbreak, which began in December and gradually increased in the number of cases affected until the middle of January, was not due to water or food, and that it had exclusively affected households suffering from influenza. (*The British Medical Journal.*) Occasionally severe diarrhœa, the most characteristic feature of which was the offensive character of the stools, had come on without any premonitory symptoms, but in the majority of cases the patients had been ailing for some days before the bowels became relaxed. These premonitory symptoms varied considerably, but they closely corresponded with those from which other members of the family had suffered; who, nevertheless, had no diarrhœa. In fact, the diarrhœa seemed generally to indicate the crisis occurring in the course of an attack of influenza, since, after the bowels had acted freely, recovery was rapid. Vomiting occurred in but few cases. It was noticed as a curious circumstance that the families affected had suffered from two, and in a few cases three, previous attacks of influenza, thus showing, apparently, a marked predisposition to the disease. Dr. Parsons has pointed out that the gastro-intestinal form of influenza is "especially noticed in children, and is marked by vomiting, diarrhœa, and other symptoms of gastro-intestinal disturbance." The peculiarity in this localized epidemic may be attributed to the fact that the proportion of such cases to those of the "nervous" and "catarrhal" types is much larger than is usually observed, possibly larger than has previously been recorded. This disproportion may be, perhaps, accounted for by the fact that the small community affected by the epidemic contained as many children as adults.

Simple and Pernicious Anæmia.—Writers of textbooks on medicine have always had a great deal of trouble in classifying the different varieties of anæmia. Some have adopted the plan of grouping them as primary (or essential) and secondary. This, of course, is open to the objection that a form of anæmia of which we know the determining cause becomes secondary, while anæmia of obscure origin is described as primary. Theoretically, they may be classified according as they are due to deficient production, or to exaggerated destruction of red corpuscles, but clinically, it is often impossible to say which is which. We are therefore constrained for the present to revert to the old-fashioned division into "simple" and "pernicious." (*The Medical Times.*) The latter has various aliases. It is termed by one "pernicious," by another "essential" or "idiopathic," and by a third "progressive" anæmia. It will suffice for our purpose to point out that this graver variety of anæmia is associated, like simple anæmia, though in a more marked degree, with a striking diminution in the number of red corpuscles. In simple anæmia, however, the diminution in number is accompanied by a more than corresponding fall in the proportion of hæmoglobin, the corpuscles losing in value as well as in number. In pernicious anæmia, on the other hand, the proportion of hæmoglobin is, so to speak, in excess—not of course in comparison with normal blood, but in comparison with blood impoverished to the same extent in respect of the corpuscular elements. The destruction of red corpuscles which is so characteristic of pernicious anæmia, takes place in the portal circulation, and the free hæmoglobin stains and deteriorates the liver, giving rise to a yellow coloration of the skin and a dark-yellow color of the urine of these patients, the latter being due to the presence of an unduly large amount of urobilin, a modified blood-pigment. So constant is this excretion of urobilin, and so easy is it of recognition, that it may fairly be accepted as the salient feature of the disease. In fact, whenever the practitioner comes across a case of well-marked anæmia, associated with a temperature above normal, a yellow complexion and a dark urine giving the reaction for urobilin, he should suspect pernicious anæmia and modify his prognosis and treatment accordingly. Iron is absolutely useless in the treatment of this affection, and even arsenic, though it seems to exert a specific action in some cases, cannot be relied upon. The first thing to do is to clear the liver by small doses of calomel, and then to combat the irregular fermentation going on in the gastro-intestinal tract by the administration of β-naphthol or salol. This treatment is based on the assumption that the destruction of the red corpuscles is the result of the action of certain organic ferments absorbed from the stomach, it having been ascertained experimentally that the condition can be artificially induced by the injection of such ferments.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, August 26, 1893.

THE PAN-AMERICAN MEDICAL CONGRESS.

THIS long-projected meeting of the medical practitioners of the two Americas, which is to begin in Washington a week from next Tuesday, September 5th, and continue in session during that and the three succeeding days, promises to fulfil the expectations of those who have labored to make it a success. The list of titles of papers to be read in the different sections is a long one, and its perusal will set at rest any fears which the friends of the Congress may have entertained as to its place among the scientific gatherings of the world. The total number of papers in the twenty sections is 661, and doubtless others will be offered at the last moment which may be read if time permits. The largest number of papers in any section (52) is in that on Gynecology and Abdominal Surgery. We notice that the Section on Orthopedics has been dropped, the papers on orthopedic subjects being listed in the Section on General Surgery. It is not from the mere number of papers, however, that we are led to look forward to an interesting meeting, but the subjects chosen are such as to warrant a belief that the scientific success of the Congress is assured. Naturally, a majority of the papers to be read are by physicians of the United States, yet a larger number than was anticipated have been offered by adherents to the Congress from the Spanish-American countries, Brazil, and the West Indies.

The Governors of nearly all the States of the Union have appointed delegates to represent the sanitary interests of their respective States. These latter number nearly three hundred in the aggregate. It will be seen from this that special interest is centring in the sections on Marine Hygiene and Quarantine, and on Hygiene, Climatology, and Demography, in charge respectively of Dr. Wyman of the Marine Hospital Service, and Medical Director A. L. Gihon of the U. S. Navy. The imminence of cholera in the East, and the perennial prevalence of yellow fever in the South, give particular importance to the proceedings of these sections at this time. From the programme published in another column it will be seen that the papers and discussions to be presented before these sections are mostly on subjects of unusual interest and international importance.

Apart from the question of papers, the Congress promises to be a success as regards the number of those in attendance. All of the countries, practically, have appointed official delegates in response to the invitation from the President of the United States, and a large number of the colonies, and a great many municipalities have likewise appointed delegates, as have also the medical organizations throughout Latin-America. Owing to the hard times, it is possible that the attendance from our own country may not be as large as it would otherwise have been; yet it is possible, on the other hand, that a number who could not spare the time, or had not the energy to devote to two large medical assemblages in one month, may now attend the Pan-American, since the Rome Congress has been postponed. We trust, indeed, that all who can will go to Washington to do honor by their presence to our guests from the sister republics and colonies of this continent, and also to aid by their contributions in making the Congress as successful financially as it is sure to be scientifically.

DIAGNOSIS OF HEREDITARY SYPHILIS.

FOURNIER insists that the diagnosis of hereditary syphilis must be based almost exclusively upon ocular evidence. Beyond a family history of infantile polymortality, verbal information has but little significance. To Hutchinson's triad of symptoms—notched teeth, interstitial keratitis, and inflammation of the middle ear—must be added three other important evidences of specific trouble that do not always receive sufficient emphasis. First, the general appearance of the patient; next, the cicatrices upon the skin and mucous membranes; and, third, the deformities of the bones. Persistent childhood best describes the bodily condition, owing to the low stature and slight frame. The scars upon the skin and mucous membranes present four definite characteristics: their size, configuration, area, and locality. They are very small, almost minute; in form like a rounded bow, an arcade, or a serpentine curve. They are arranged in groups joined at the side; and are found at the commissure of the lips, about the circumference of the nose, in the throat, and particularly upon the buttocks and in the lumbar region. In the bony skeleton are the most strongly marked, the most profound and persistent lesions, easily discovered in the skull, in the face, in the bones of the extremities, most notably in the tibia. The forehead bulges outward, or may be keel-shaped, or may present symmetrical protuberances. There is often marked increase in the transverse diameter of the head, and the lateral halves of the cranium often show marked asymmetry. The characteristic deformity of the face is that of the nose. In the first type the upper part of the nose seems to have fallen in, and the tip turns up; in the second, the lower portion of the nose is shortened, and appears in some way to be absorbed into the upper part. There are also less typical nasal deformities, as when the nose is flattened at the base or badly formed, the result of simple dystrophy, and not of necrosis. Protuberances and hyperostoses are found at the level of the epiphyses, especially noticeable at the upper extremity of the tibia and the lower extremity of the radius and ulna. But the tibia is the direct revelation of syphilis. Its form alone will reveal this disease. It is large, thick, and misshapen, much widened and depressed in its middle portion. The crest is so much increased in size as to present a plane face. In general effect the bone is like the blade of a sword. This conformation is never found in any condi-

tion other than hereditary syphilis, of which it is the pathognomonic sign. Chronic lesions of the testicle are of frequent occurrence. This, together with a history of middle-ear trouble, interstitial keratitis, notched teeth, small scars upon the skin and mucous membrane, the imperfections of the bony skeleton, the arrest or anomalies of bodily development, and the special condition of the tibia, render the retrospective diagnosis of hereditary syphilis comparatively easy.

THE QUESTION OF BROTHERLY LOVE.

Brotherly love seems to be at a discount at Hot Springs, Ark., if one may judge by the sentiments of the editor of the *Hot Springs Medical Journal*. "Doctors hate Each Other" is the text, and the comment is this:

"*Humanum ingenii, odisse quem laeseris*, or words to that effect, is the way Tacitus applies the idea to the human race; but had he been acquainted with the modern profession of medical meanness, he would doubtless have changed the wording to read as an axiom, 'It is the mark of the doctor's (?) profession to hate those they have injured.' For doctors (?) are mean, and perhaps in no other profession does there lurk and skulk around more uncalled-for, more childish, more cowardly hatred than in the profession that is supposed to battle in brotherly love and harmony for the general welfare of fellow-man. A physician will sometimes listen to evil reports of a brother physician from the lowest source of gossip (for doctors are often thrown with the lowest classes), and will repeat it, much to the annoyance of the one maligned. When he finds what a wrong he has done by his tattling, he hangs his head on meeting the injured man; this makes him feel his innate meanness, and somehow or other a bitter feeling springs up in his heart against his victim, which slowly, but surely, grows into hatred."

We print all this because it probably represents in a degree the state of affairs in some towns of this great country. It is certainly gross exaggeration, and for many places entirely unjust and untrue. There is a very great amount of friendly feeling among the physicians of this and many other cities. Our society meetings, great and small, are always social reunions, which are a source of great pleasure. There exist the warmest friendships among us. In fact, there is no other calling where there is so much loyalty to each other, and where mutual help is so freely extended. It is a by-word among all that doctors "stick to each other."

The jealousies and backbiting which do exist are nourished mainly by men of petty minds and small attainments. The measure of professional advance is pretty accurately determined by the amount of local quarrelling. In proportion as the standard of medical and mental attainment increases the small jealousies disappear. We fear that Hot Springs ranks low.

Living Bacteria in the Mails.—The Postmaster-General has issued an order to the effect that disease germs, or other things of like character, no matter how securely put up, are of the character of poisons and extremely dangerous to health, and that they are therefore absolutely unmailable. Postmasters are instructed to see that no such things are allowed entry into the mails.

INORGANIC SALTS AS FOOD AND STIMULANT.

A good deal of attention has been called to the inorganic salts as promoters of nutrition and therapeutic agents of the tonic class. There have been published several formulæ for what is termed "artificial serum," consisting of various combinations of salts which are used for hypodermic injections. We read of neuralgias cured by injections of sodium phosphate, and of surprising tonic effects resulting from other injections. Whether this is another chapter in suggestive medicine it is difficult to say. There is, however, no doubt that inorganic salts have more than simple mechanical and chemical functions in the body. Professor R. H. Chittenden recently called attention to this in an editorial article in *The Dietetic and Hygienic Gazette*. Thus he says:

"Calcium phosphate, for example, is unquestionably just as important a factor in the life of the highly developed human organism as it is for the life of unicellular organisms, and this irrespective of the part played by this salt in the formation of the bony skeleton. All biologists are familiar with the need which micro-organisms have for calcium phosphate; it is an invariable constituent of all culture media, and without it growth and development become an impossibility."

Mineral salts have also been shown to have an actual stimulating effect on the heart. Professor Howell found that blood serum from which all proteids were removed had the power of stimulating the isolated frog's heart so that it will continue to beat normally for many hours without the addition of any other agent. Thus, in one experiment, the heart was first isolated and thoroughly washed out with normal saline. The solution of the inorganic salts of the serum was then injected and kept in the circulation. The heart continued to beat for from eight to thirteen hours. This could not have been due to any nourishment furnished it, but simply to some direct or indirect stimulus to the heart muscle.

It does not seem reasonable to infer from this, as some do, that the hypodermic injection of a teaspoonful of artificial serum can do any good. The best way to secure the good effects of the inorganic salts is by proper feeding.

Catherine de Medici's Doctor.—Pharnelius, like many other physicians, was much addicted to philosophy and mathematics, but, having taken to medicine, he speedily attained a great practice. Henry II. as Dauphin, and afterward as King, was his constant friend. Among the most grateful of his patients was Catherine de Medici, who believed that his skill had saved her from a state of childlessness, and who gave him, on the birth of her first-born, $10,000, ordering that a like sum should be paid to him at the birth of each succeeding son or daughter. I think that Cardano liked Pharnelius better than he liked Sylvius. He says he was a pale, lean man of about fifty, who loved his study, and was full of domestic affection. He was the Professor of Medicine in the University, and the first Court physician, but he must have puzzled Cassanate greatly, for he had an undisguised contempt for Court society.—*Blackwood's Magazine.*

The Pacific Medical Record is a new monthly published at Portland, Ore., and edited by Dr. Henry W. Coe. It fills a place by supplying a journal for the Northwest.

News of the Week.

Yellow Fever.—The case of Dr. Branham, of the Marine Hospital Service, in Brunswick, Ga., who was attacked with suspicious symptoms, has been declared to be one of yellow fever. Another case of the same disease has developed there, and, as the patient had not been in communication with Dr. Branham, it is feared that there are other foci of infection which have not yet been discovered. A tramp steamer from Vera Cruz arrived at Port Tampa, Fla., on August 18th. Soon after her cargo of sisal hemp was discharged several of the crew were taken ill and one died with symptoms of yellow fever. The vessel was at once sent to quarantine, and the town is now under surveillance by the State Board of Health. The quarantine at Pensacola has been raised, no new cases of a suspicious nature having occurred. A Norwegian bark with yellow fever aboard has been detained at quarantine at Wilmington, N. C.

Dr. H. Radcliffe Crocker, of London, arrived in New York recently on his way to Chicago and to the meeting of the Dermatological Association in Milwaukee.

Camphorated Carbolic Acid.—Dr. S. W. S. Toms adds to an article on this substance, published in the MEDICAL RECORD of August 19th, that it has been found to have no effect upon polished steel, and that it ought therefore to be the most satisfactory means for preserving surgical instruments, needles, etc., from rust and keeping them antiseptic.

Dr. George H. Walling died at his home in Louisville on August 21st, aged nearly seventy-four years. He was one of the oldest physicians in Louisville, having practised his profession there for more than half a century.

Pan-American Medical Congress.—The following is a list of papers to be read in the sections named:

Section on General Medicine.—"Formas del Impaludismo y Medio de Reconverlas," by Francisco A. Risguez, of Caracas, Venezuela; "Cold Steel as an Antirheumatic," by W. K. Vance, of Bristol, Tenn.; "Cholera Asiatica—1892," by J. D. Burch, of Aurora, Tex.; "Facts in Stethoscopic Percussion," by Henry Sewall, of Denver, Col.; "A Study of some Cases of Chronic Diabetes," by N. S. Davis, Jr., of Chicago, Ill.; "Typhoid," by W. C. Dabney (University of Virginia); "A Case of Acromegalia in a Giantess," by Woods Hutchinson, of Des Moines, Ia.; "The Value of Rest as a Therapeutic Agent in Chronic Pulmonary Tuberculosis," by Karl von Ruck, of Asheville, N. C.; "A New Anærobic Bacillus of Malignant Oedema," by F. G. Novy, of Ann Arbor, Mich.; "Progressive Pernicious Anæmia," by Judson Daland, of Philadelphia, Pa.; "On the Occurrence of a Form of Chronic Bright's Disease other than Typical Fibroid Kidney without Albuminuria," by D. D. Stewart, of Philadelphia, Pa.; "De la Buba," by Luis Razetti and N. Guardia, of Caracas, Venezuela; "La Folie chez le Nègre," by J. B. Da Lacerda, of Rio de Janeiro, Brazil; "La Cause de la Fièvre jaune," by J. B. Da Lacerda, of Rio de Janeiro, Brazil; "A New Disease of the West Indies," by Cuthbert Brown, of Barbadoes, West Indies; "The Bacteriology of Dengue Fever," by J. W. McLaughlin, of Austin, Tex.; "Culture of Anærobic Bacteria," by F. G. Novy, of Ann Arbor, Mich.; "Consideraciones sobre dos Casos de Anæmia por Ankylostoma duodenale, observados cual Hospital Victor Manuel de Lima," by J. B. Agnoli, of Lima, Peru; "A Contribution to the Study of Prolonged Intermittent Fever," by David Lobo, of Caracas, Venezuela; "The Nature of the Germicidal Constituent of the Blood Serum," by Victor C. Vaughn, of Ann Arbor, Mich.; "On Vaso-motor Ataxia," by J. Solis Cohen, of Philadelphia, Pa; "Recent Experiences in Croupous Pneumonia, with Observations on Treatment by Subcutaneous Injection of Saline Solutions," by R. F. Cunningham, of Birmingham, Ala.; "Cholera: its Diagnosis, Prognosis, and Treatment," by J. M. Hurley, of San Bernardino, Cal.; "Colera Morbo Asiatico," by Santiago Hernandez, of Santa Clara, Cuba; "The Importance of Eliminating Pelvic Diseases in General Diagnosis," by Mary H. McLean, of St. Louis, Mo.; "Clinical Notes on Amœbic Dysentery," by H. A. West, of Galveston, Tex.; "Some American Ideas about Chronic Diarrhœa," by Ephraim Cutter, of New York, N. Y.; "Tratamento medico del Vomito negro," by Segundo Bellver Mateo, of Havana, Cuba; "The Principles of Immunity and Cure of the Infectious Diseases," by Victor C. Vaughn, of Ann Arbor, Mich.; "Forced Respiration—Fell Method—A Plea for its General Adoption in Hospital and Naval Practice," by George E. Fell, of Buffalo, N. Y.

Papers by Manuel Carmona y Valle, of City of Mexico, Mexico; E. L. Shurley, of Detroit, Mich.; J. C. Wilson, of Philadelphia, Pa.; Charles G. Stockton, of Buffalo, N. Y.; F. Peyre Porcher, of Charleston, S. C.; J. H. Musser, of Philadelphia, Pa.; George Dock, of Ann Arbor, Mich.; W. C. Christopher, of Chicago, Ill.; C. S. Bond, of Richmond, Ind.; D. W. Prentiss, of Washington, D. C.; R. L. Miranda, of New York, N. Y.; William Osler, of Baltimore, Md.

Section on General Surgery.—"The Treatment of Pott's Disease of the Spine," by A. B. Judson, of New York, N. Y.; "The Probable Cause of Limp in the First and Second Stages of Hip joint Disease," by Harry M. Sherman, of San Francisco, Cal.; "Mechanical Treatment of Osteo-arthritis of the Knee," by Henry Ling Taylor, of New York, N. Y.; "Ununited Fracture," by Llewellyn Eliot, of Washington, D. C.; "Some Points in the Surgical Treatment of Appendicitis," by Augustus P. Clarke, of Cambridge, Mass.; "A Brief Splint Technology for Surgeons," by Edward A. Tracy, of Boston, Mass.; "Reconstructive Surgery," by Thomas G. Maghee, of Rawlins, Wyo.; "Urethral Polypus in the Male," by R. Menocal, of Havana, Cuba; "Simplicity in Surgery," by Robert W. Johnson, of Baltimore, Md.; "A Report of Four Cases of Brain Surgery," by Andrew J. McCosh, of New York, N. Y.; "Sondas y Bujiras Gercas del Dr. Castano," by Alberto Castano, Buenos Aires, Argentine Republic; "Tratamiento quirurgico de la Fiebre amarila," by Segundo B. Mateo, of Havana, Cuba; "In what Class of Cases is Drainage Required?" by H. O. Marcy, of Boston, Mass.; "Causation, Pathology and Treatment of Carbuncle," by David W. Code of Rules for Handling an Epidemic Disease that Breaks out on Shipboard. Disinfection of Passengers and Crew During a Voyage. Location and Arrangement of Ship's Hospitals;" "Arrangement of Detail and Equipment of Quarantine Stations; *a*, Inspection Stations; *b*, Local Quarantine Stations; *c*, Refuge Stations. Methods for Handling Infected or Suspected Vessels. Interstate and Inland Quarantine. Sanitary Cordons; Camps of Refuge; Camps of Probation. Recent Improvements in Hospitals for Infectious Diseases. Railroad Inspection and Quarantine. Length of Time Vessels Should be Held in Quarantine. Conditions that Should Determine Proclamation of Quarantine Against a Country;" "Under what Requirements may Passenger Traffic be Carried on between a Port Infected with Yellow Fever and a Southern Port of the United States During the Summer with the Least Obstruction to Such Traffic;" "What Merchandise Should be Considered as Requiring Treatment if Shipped from a Port or Place Infected with Cholera, Yellow Fever, or Small-pox?" "Methods of Disinfection: *a*, Persons; *b*, Baggage; *c*, Cargoes; *d*, Vessels. Recent Improvements in Quarantine Appliances; Steam Chambers; Sulphur Furnaces. Liquid Sulphur Dioxide as a Disinfectant. Treatment of Ballast: Water; Solid. What Time Should an Infected Vessel be Detained in Quarantine? *a*, For the Cholera; *b*, For Small-pox; *c*, For Typhus Fever; *d*, For Plague; *e*, For Yellow Fever. Methods of Disposal of the Bodies of those that Die While in Quarantine."

Pan American Medical Congress.—*Transportation.*—The Transportation Committee of the Pan American Medical Congress makes the following announcement in regard to reduced rates for delegates and members of their families from all sections of the United States, also from the Pacific coast, ports of Mexico and Central America. Delegates from the territory of the Trunk Line Association east of Pittsburg and Erie and Buffalo, from points in the New England States in the territory of the New York and Boston Lines Passenger Associations, from points in Central Traffic Association, embracing the territory from Buffalo, Pittsburg, and Parkersburg, W. Va., in the east to Chicago and St. Louis on the west, and from points in the Southern Passenger Association, embracing the territory south of the Ohio and Potomac Rivers and east of the Mississippi River, will be granted one and one-third fare on the certificate plan. Delegates from points west of the territory of the Central Traffic Association can avail themselves of the World's Fair excursion tickets as far as Chicago and secure from Chicago the fare and a third on the certificate plan to Washington. Delegates from South America, the Pacific coast, Mexico, or Central America, can secure from point of starting round trip tickets to Chicago at the World's Fare rate either by way of San Francisco or New York. The latter can secure from New York the fare and a third on the certificate plan on application to the ticket offices of either the Penn. RR. or B. & O. RR. The certificates referred to must be secured at the time of the purchase of the ticket to Washington on which, properly signed by Dr. H. L. E. Johnson, Chairman of the Transportation Committee, the reduced rate will be allowed returning. To be more specific, the full fare is paid on the going trip to Washington, and a two-thirds reduction is allowed when the ticket is purchased in Washington for the return trip. These certificates must be obtained at the ticket offices at the time the ticket is purchased. The purchaser must be sure to state that he is a delegate and will be in attendance at the meeting.

Progress of the Cholera.—No important change in the cholera situation has taken place during the past week. The disease is said to be abating somewhat in Naples, though there are many cases reported from small towns in the neighborhood of that city. It still exists in Campobasso and other places in Central Italy. A suspicious case has been reported from Palermo. In Vienna there are said to be about twenty-five new cases each day, and the disease has broken out in the military camp at Bruck, twenty three miles from Vienna. The usual number of cases are reported in Brahilov and Sulina in Roumania. In Galicia the epidemic is said to be abating, but the disease has broken out in several places in Hungary. The number of new cases in Russia during the week ending August 22 was 2,359, and the number of deaths 934. Cholera is declared to be epidemic in St. Petersburg, and is still active in Moscow. The reports from our quarantine station have been favorable. No new cases of the disease have been brought here from Naples or from any other foreign port. The cases discovered upon the Karamania have nearly all recovered. One man who was convalescing from cholera died of pneumonia. A man died in a lodging-house in this city a few days ago after having suffered from diarrhœa and vomiting all night. He received no medical assistance, but the body was examined by an officer of the Health Department, and the disease was declared not to be cholera.

Dr. William S. Hurd, of Paterson, N. J., died in that city on August 18th, after a long illness. He was born at Fishkill Landing, N. Y., in 1847, and was graduated from the College of Physicians and Surgeons in this city in 1877. In 1878 he was elected assistant city physician of Paterson, and served five terms by yearly re-election. He also served a three-year term as Coroner of Passaic County.

Four Physicians Sued.—A boy died in this city, in June, 1892, while under the influence of chloroform, and although the coroner's jury of medical men exonerated the physicians present at the operation from all blame, the parents of the child claim that the anæsthetic was carelessly administered, and have sued the attendants for damages. The boy was four years of age, and the damages claimed are $5,000.

A Suicidal Mania is said to be prevailing in London and Paris at the present time, many of the victims being young men and women in comfortable circumstances who have no apparent cause for putting an end to themselves. It is attributed by some to the long spell of hot dry weather which has visited Europe this summer.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Sixty-first Annual Meeting, held at Newcastle-on-Tyne, August 1, 2, 3, 4, and 5, 1893.

(Special Report to the MEDICAL RECORD.)

SECTION OF MEDICINE.

FIRST DAY, WEDNESDAY, AUGUST 2D.

DR. W. MILLER ORD, PRESIDENT, IN THE CHAIR.

Discussion on Chronic Glycosuria.—This discussion was opened by SIR DYCE DUCKWORTH, who said that glycosuria was well known to be a far more formidable disease in early youth than it was in adult life. There was some difficulty in clearly defining where glycosuria ended and diabetes commenced. Clinical knowledge of diabetes was very extensive; but the morbid anatomist was still puzzled at the want of lesions found after death. Claude Bernard, Pavy, and others had shown that both the nervous system and the liver were implicated in the disease; but it was difficult to account for the more acute character it exhibited in youth. In cases of "lean" diabetes, it had been said that the pancreas was affected; but it was too rash generalization to assert that all emaciated diabetics had the pancreas affected. Cancer of the pancreas often produced no glycosuria. Lancereaux had asserted that fat diabetics had no pancreatic affection. Acute diabetes occurred in middle life when the pancreas was intact. He maintained that only glycosuria with polyuria ought to be considered as diabetes. Glycosurics were usually active persons with good appetites, and not infrequently drinkers of alcohol and free livers. Much alcohol with plain living did not produce the disease. The urine was bright and clear, and tongue clean. Some diminution of sexual desire was often present, but, on the whole, the patients usually had no bad symptoms. Many complained of weakness, and pain in the back sometimes was complained of. The disease came to be recognized generally about the age of fifty. Carbuncular troubles were rare. The phalangeal joints were often enlarged. Large consumption of food and irritability of the great nerve centres were apt to produce gout and diabetes. In many cases, the evil might originate from the brain. Morbid histology and pathology had as yet thrown no light upon this disease. We need not hope to see a sclerosis of any part in future investigations; but experiments on animals might clear up the difficult problem. Glycosuria was often accompanied by an excessive secretion of urea. Sometimes glycosuria and albuminuria alternated. Addiction to strong wines, and grief, were given as causes, and Dr. Harley said that alcoholism was the commonest cause of diabetes. Diabetics were very vulnerable and liable to gangrene of sores. If untreated, many of them rapidly succumbed. Cataract was rare in chronic cases. As to the diet of glycosurics, sometimes they required no change of food, but variety should be given. Opium was not of use in slight glycosuria. Arsenic was often of service in five-minim doses. Dr. Murray used cocaine and restricted diet. With respect to hygiene, regular habits and action of the skin should be attended to. Mountain districts were better than seaside resorts, and the country than the town. The pleasures of society should be shunned. Cases associated with gout did well. With due care advanced age might be attained; but there were many dangers to be avoided by the diabetic patient which should make him always on his guard.

PROFESSOR GAIRDNER, of Glasgow, said he could not say anything on the general questions, but narrated the case of a friend who died in 1889. In this case there was no evident mental sorrow to produce the disease. He was a man disposed to corpulence, but who liked active exercise and took long walks. He was a little weak in one of his knees. This patient was glycosuric. The patient went to Dublin, and saw Dr. R. Macdonnell. He was put on the usual regimen, for some years abstaining from starch and sugar. The disease lasted for many years. There was no gouty history in his family. He was in a government office, and declined entering on a higher step because of his illness. During his youth he had passed much uric acid. Perhaps his mother had been glycosuric. Patient's age at death was sixty-four, having been glycosuric for about thirty years. He had had an attack of gout in Rome, and his foot took on gangrene, and this carried him off.

DR. SAUNDLY, of Birmingham, said he thought that Sir D. Duckworth had hardly been able to define clearly the group of glycosurics he had desired to do. He had seen that many cases of glycosuria had ended in true diabetes. The discovery of the existence of glycosuria was no reason for treating it; and the proper therapeutics consisted in treating symptoms, but not glycosuria. He could not speak very confidently of the action of any drug on diabetes.

DR. W. R. THOMAS, of Bournemouth, mentioned the case of a gentleman, aged thirty-five, with diabetes. This gentleman was suffering from polyuria. He had been worrying a good deal at home about his business. He, Dr. Thomas, advised retirement from business, and patient got greatly better. Another gentleman became much worried with a drunken son, from whose conduct he suffered much. He was treated in the ordinary way. Careful hygiene and the giving up of business did much good. Since he, Dr. Thomas, had looked for worry as a cause of this disease, he had constantly found it to exist. His experience was that sometimes it was not necessary to be very strict in dieting; but he recommended much exercise.

DR. C. R. DRYSDALE, of London, said that it was interesting to hear from Sir D. Duckworth, that neither physiology nor pathology had thrown much light on the causation and treatment of the fatal disease, diabetes. He could not agree that it was useful to define accurately glycosuria from diabetes. A few years ago it had been the fashion to define between albuminuria and Bright's disease; but such refinements were not useful, he thought, in the treatment of disease. He thought that Claude Bernard's hypothesis that the liver secreted sugar, threw light on the value of animal diet in diabetes, and as the disease progressed its greater unamenability to dietetic treatment. It had been questioned whether the duration of the disease could be much affected by diet; but certainly meat diet gave the patient a far more enviable existence than without it. Rich people alone could be well treated in this sad disease, which rarely lasted as long as twenty years. He once recommended a workingman to seek New Zealand, where he could get meat thrice daily, and this advice was followed by excellent results. Exercise was useful.

DR. GARRETT ANDERSON said that of late she had abandoned the term glycosuria, and used the term diabetes. One of her patients, a little boy, had glycosuria. He was nine years of age, and she had given a very bad prognosis when she first saw him; but he kept lingering on wonderfully. A lady went on passing sugar and albumin for eighteen years. She considered exercise in the open air as very beneficial. And, as to diet, she had found often how difficult it was to get patients to eat meat. A great deal of out-door exercise was good.

DR. MARKHAM SKERRIT said that he also could not recognize any very clear line of demarcation between glycosuria and diabetes, although certainly in some cases there was a persistency of glycosuria without diabetes. With regard to treatment, it must be remembered that we had to do with glycosuria, and he was much in favor of arsenic and a large amount of exercise in the open air.

DR. SHUVLETON SMITH, of Bristol, showed a drawing of a cervical tumor of the cord, which had been accompanied by glycosuria. He asked whether it was possible to define so sharply cases of glycosuria as had been tried

by Sir D. Duckworth, and agreed with Dr. Drysdale that this attempt resembled that of diagnosing between albuminuria and Bright's disease, and that it was a very difficult, nay, impossible feat. The disease of glycosuria was far more common than was supposed, and was also much more amenable to treatment than many would allow. Gout and hæmorrhoids often alternated with glycosuria. Thus he had a patient who, whenever he had loss of blood at stools, lost sugar in his urine. The gouty diathesis was intimately connected with the glycosuric, and deficient elimination was the proximate cause of the symptoms of diabetes. It was the duty of the practitioner to make way against this state of things. There was much evidence to show that plenty of fluids should be taken in glycosuria, so as to give an ample flushing out of the intestine. Perhaps alkalies might be of service in some cases. Alkaline saline drinks were occasionally of use.

A member then spoke who desired to remain anonymous, as he was himself suffering from glycosuria; apparently he was about thirty years of age. He said that recently he had been suffering both from polyuria and glycosuria, with urine of 1.040 specific gravity, and one hundred and fifty ounces being passed in the twenty-four hours. On careful dieting, the sugar fell off in quantity, and also the amount of urine, and he felt better at once. The physician he consulted advised him not to take toast, as in it there was more soluble matter than in bread. He used the diabetic bread and found it quite agreeable. Polyuria had disappeared in his case, and he now drank only about fifty ounces. At times he was very weak. He had a small gouty nodule on one of his fingers. He slept well, but wakened up with stiff joints. He had lost a stone in weight and had bilious attacks frequently. He had at present only three grains per ounce in his urine. He took one-eighth grain of codeia with cascara sagrada and nux vomica, all of which was easily carried about with him. He attributed his attack to overwork and anxiety, as he had worked night and day some years ago to get another degree, while carrying on a large practice. He had been nearly a total abstainer from alcohol, and had much walking exercise every day.

Dr. Redmond, of Newcastle-on-Tyne, thought that the term diabetes was misleading. He would use the word polyuria to denote excess of urine, and qualify it with the word saccharine or simple as the case might be. He narrated the case of a gentleman aged sixty, who passed ninety ounces of urine with four grains of sugar in the ounce. He suffered from much mental strain, and took a good deal of alcohol. He gave him saccharin and cut off his starchy food, following this up with alkalies and nux vomica, and he was much benefited.

Dr. Ord, of London, said that he considered that glycosuria should be looked upon as a symptom. The practitioner was strictly bound to look narrowly at all causes of this disease. Hereditary transmission was probably one cause to be taken into account. The disease was sometimes connected with angina pectoris, sometimes preceding attacks of this disease, sometimes following after such attacks. In such cases there was much arterial tension, and nitrite of amyl was sometimes a valuable remedy. He, Dr. Ord, had some years ago spoken of gout of the liver, an expression he still adhered to. Causation should be attended to in the treatment of every case of glycosuria. A highly restricted diet could not be continued indefinitely, and in some cases patients thus treated became quite emaciated from such vigorous treatment, and succumbed to it. Regular exercise in the open air, eight or ten miles daily, was of service; but fatigue was hurtful.

Sir Dyce Duckworth, in reply, said the discussion had been most interesting and useful. The present teaching about the disease was nebulous, and such discussions were most useful to teachers for their lectures. He observed that many of the speakers were inclined to class glycosuria as chronic and mild diabetes. This he could not admit. A most important point in the future would be to examine the hereditary histories of all patients, by means of portraits, etc., and to see whether the tissues of the patient were intact. This was a guide to prognosis. The rank of the patient was important, as Dr. Drysdale had said it was a bad thing for a poor man to have glycosuria who could not command good diet. The glycosuria of children was the gravest of all. Under eighteen the disease was most acute, and probably often hereditary in origin. Many patients had no thirst and did not waste, even when passing much urine. He objected to call all these cases merely acute or chronic diabetes. He would say one word of warning about much exercise. He had lived with a diabetic patient and closely watched him, and would say that exercise was good, but only within the limits of fatigue. Rigid diet could not be tolerated by any human being for more than a few weeks, and was a cruel treatment, so that patients often lost their morale and only pretended to make use of it. Finally, he had a high opinion of arsenic in glycosuria.

Myxœdema.—Dr. George Murray showed a woman with well-marked symptoms of the disease, who, after a lengthened treatment, had been cured by the injections of (ten minims each injection) glycerine extract of thyroid glands. She had been treated for more than two years, and whenever the treatment was intermitted the symptoms returned. In two patients treated by glycerine extract of thyroids, cardiac weakness had carried off the patients, who took too much exercise for their strength. Such patients took a fluid drachm of thyroid extract per week. He also showed lantern slides of several patients, both male and female, which exhibited the appearances seen before and after the cure of the affection.

Professor Oliver, of Newcastle, said that myxœdema was rather an uncommon disease. In one instance, a case of it had in his experience recovered spontaneously. His own clinical experience corroborates fully all that had been said by Dr. Murray as to the enormous value of thyroid injections.

Dr. Allison showed a female patient who had developed myxœdema in pregnancy, and had lost the hair of her head, and had many of the well-marked features of the disease. Another patient, female, aged fifty three, was first seen in July, 1886. Her pulse was 80, her hands much swollen, and she was getting bald. The urine was alkaline and loaded with lithia. Next, a male patient was shown who had been cured of this disease, which was much more frequent in women than in men. All of these cases had been treated by portions of the thyroid of the sheep slightly cooked. In this case the eyebrows returned first of all, and afterward the hair of the scalp. He took one lobe of a sheep's liver daily. This was quite a wonderful treatment. The active principle in the thyroid was, he thought, a salt. One patient he had treated was covered with eczema before treatment, and this speedily disappeared.

Sir Dyce Duckworth mentioned a case of myxœdema which he had treated with the most perfect success. This was, he said, one of the most marvellous discoveries of modern times, and it might open up new possibilities in therapeutics undreamed of at present. But he would caution his hearers not to be led away into all sorts of experiments with thyroid glands in all sorts of diseases, for such new departures were apt to bring discredit on the practice of medicine, and make the public suppose that medical men were not so grave and scientific as they ought to be.

A member asked whether thyroid extract had been used for the treatment of ordinary baldness, and what had been the result.

Dr. Ord said he did not know in how far it might be possible in the future successfully to treat cases of baldness, but hitherto thyroid extract had not often been tried, and the results had not been encouraging. The growth of the hair sometimes was improved by jaborandi. In one case, after profuse sweating the hair began to grow and of a better color than previously. The cure of myxœdema without treatment was most exceptional and hope-

less. Dr. Garrett Anderson's case showed that it might occasionally occur and disappear spontaneously, but that was rare.

Professor Oliver said that he had noticed a distinct pause between inspiration and expiration in some patients with myxœdema.

Dr. Ord said that before Dr. Murray's experiments were known, he had successfully treated myxœdema by pieces of goitre which he had transplanted. The treatment by thyroid could not be called a palliative one. He held it as certain that a lengthened discontinuance of treatment led to relapse. A patient he had had in St. Thomas's Hospital was getting steadily worse, and could not bear cold. A whole sheep's thyroid was daily administered, and her temperature rose to 104° F. Hence it was well to be cautious in the use of this remedy. He began with twenty minims of glycerine extract daily, and this did good in a few days. The voice gradually got stronger. There was great variation in the physical state of patients. In two cases albuminuria disappeared after the treatment. Probably heredity played a part in myxœdema which might gradually be cleared up. Meanwhile nothing was known in this matter. The meeting then adjourned.

Second Day, Thursday, August 3d.

Dr. Ord, President, in the Chair.

Atrophic Paralysis.—Dr. William Ferrier read a paper "On the Pathology and Distribution of Atrophic Paralysis." The streaked muscles were, he said, quite independent of the anterior columns of the cord. There were several types of atrophy. There were hereditary cases, etc. Juvenile muscular atrophy attacked the muscles of the shoulder first, and later on the lower extremities. All of these types agree in many respects. The pseudo-hypertrophic paralysis of the lower extremities was one form. It had generally been supposed that the hypertrophy of muscles was dependent on nervous weakness; but there was some evidence to show that the muscles might be primarily attacked. There was usually no visible lesion of the anterior horn of the cord. It seemed a large assumption that a mere dynamic alteration of the anterior columns could account for such severe lesions of the muscles. The deltoid, in adult life, was often affected first, not so in children. This was a great objection to the hypothesis of nerve lesion being the cause. Lesions of the peripheral nerves formed a second group. Those muscles became paralyzed which took their innervation from a certain nerve. Motor conduction might be entirely blocked, while sensation went on as usual. Disease of the recurrent laryngeal caused first paralysis of the crico-arytenoid muscles. The abductor muscles succumbed more quickly than the adductors. Polio-myelitis was a common cause of paralysis of muscles. The peripheral nerves were changed in such cases by poisoning with alcohol, lead, and other poisons. Special poisons had special affinities for special muscles. This had been explained by Erb to show dynamical affections of the anterior cornua of the cord. He thought that the extensor nerves succumbed more quickly than the flexors. In hemiplegia and paraplegia, this weakness of the extensors was plainly seen. He considered that there was also a central affection of the cord. This accounted for the early affection of the deltoid and other extensors. It was not easy to understand why lead should chiefly affect the upper extremity, while alcohol affected the lower limbs. The diphtheric poison chiefly affected the ciliary muscles of the eye. Nicotine first paralyzed the ciliary muscles, and then the muscles of the eyeball. The essential cause of the atrophic paralysis in other palsies was central. Peripheral paralysis did not depend on the muscular nerves. The centre for labio-glossal-pharyngeal paralysis was a separate one.

Ophthalmoplegia was sometimes associated with facial paralysis. In bulbar paralysis facial palsy also occurred. The orbicular oris and the tongue were innervated from the hypoglossal nucleus. In some cases of bulbar paralysis, it was difficult to give a good account of the causation. A muscle might be paralyzed in one function and not in the other. It would seem impossible that one muscle could be affected from a central lesion. The intrinsic muscles of the hand were represented by the lower part of the cervical region. All the muscles of the upper extremity might be attacked before the supinator longus. In the lower extremity, the tibialis anticus sometimes escaped, while the other muscles were affected, showing that it had a separate centre. Perineal muscular atrophy was hereditary. It began in the lower extremity, and probably the intrinsic muscles of the foot were first attacked. Changes took place in the peripheral muscles. Probably there was here an affection of the anterior columns of the lumbar column. It was myo-neuropathic in its character. The wasting took place occasionally very rapidly. Microscopic observation failed to discover any disease of the nerve in such cases. It was probably a neurosis. He had recorded a case where wasting on one side took place after amputation at the wrist.

Dr. Alexander Bruce referred to a case admitted into the Royal Infirmary, Glasgow, with rheumatism and syphilis. Both ankle-joints, knee-joints, and elbows were affected. On July 7th, he complained of weakness of the arm, which had come on since he had entered hospital. There was considerable wasting of the muscles of the upper extremity, deltoid, and others, such as supra- and infra-spinatus muscles. There was no pressure on any point of the nerves. The action of the muscles to electricity was remarkable. There was only slight evidence of reaction to continuous current. There was no difference in reaction on the two sides. The interrupted currents gave nearly similar results. There was no evidence of neuritis, and electricity did not indicate profound lesions. He thought the rheumatism of the joint of the finger had been the cause. The rheumatism had produced some dynamical effect. This was very different from what occurred in chronic rheumatic arthritis.

Dr. Handford said that occasionally muscular atrophy was preceded by induration. In a patient addicted to rum the deltoid, biceps, and other muscles became affected. In the course of a year his muscles began to recuperate. There was great anæsthesia over the muscles. There was neuritis in this case, but redness over the muscles.

Dr. Cowley said a family had been under his care for a few years with pseudo hypertrophic paralysis. Some members of the family exhibited this disease in varying degrees. Two boys in the family had such hypertrophy of the pectoralis as to appear to have a mammary gland. A boy, aged four, could only ascend the stairs with much difficulty. A third member of the family, a boy, was much affected, and three other children more or less affected.

Dr. Grainger Stewart said that it was charming to hear the great clearness of Dr. Ferrier's paper. He spoke of the atrophy of muscles after rheumatic affections. One patient's deltoid in one night began to atrophy and rapidly disappeared. With regard to prognosis, he had learned to be less afraid of nerve-origin cases. The value of strychnia subcutaneous was twice as good as by the mouth.

Dr. Handford said that he could corroborate Dr. Stewart's remarks. If after three months of treatment no improvement took place, the case might be considered hopeless, but if taken early nervous diseases often rapidly improved.

Dr. Drysdade greatly admired the progress in diagnosis shown in Dr. Ferrier's paper since the days of Duchenne and Brown-Séquard; but was sorry to say that the treatment of such diseases was still in a most melancholy condition, and the prognosis of paralysis, whether syphilitic or otherwise, usually gloomy.

Dr. D. Ferrier said that he agreed with the use of strychnine as recommended by Dr. Grainger Stewart, and

spoke hopefully of the future in the treatment of nervous diseases.

Heredity in Phthisis.—Dr. Solly, of Colorado, read a paper on the "Effect of Heredity on the Progress of Phthisis." He mentioned that in his practice about fifty per cent. were hereditary. Women had a higher tendency to heredity in this disease than males. Those who inherited had a worse prognosis than others, but were more careful in attempting to ward off the disease which they knew they were liable to. There was no time for debate given, which was deplored by Dr. C. R. Drysdale and others.

Thoracic Aneurism.—Dr. Drummond, of Newcastle, gave a demonstration on thoracic aneurism. During the last ten years one hundred and fifty cases of thoracic aneurism had been treated in Newcastle infirmaries. He had noted fifty cases carefully in the post-mortem room. He exhibited nine patients. A great number of lantern slides were shown of different varieties of aneurism. As to prognosis, men may go on for fifteen years working fairly hard. As in recurrent laryngeal, the voice might not be affected at all in abductor paralysis.

Dr. Drysdale was pleased to hear that aneurism was probably syphilitic in origin. If so it might, of course, be prevented if people would be careful.

Dr. Redmond said he entirely agreed with Dr. Murray, that syphilis was the great cause of aneurism. He did not think that one hundred and forty five cases in ten years was very great. The laxity of the syphilitic memory was remarkable. Zeissl said that many cases get syphilis without knowing it, and this was quite true.

Dr. Carlisle had seen few cases of thoracic aneurism, and could not help thinking it must have something to do with occupation.

Dr. Lane did not see fifty cases of aneurism for twenty years, and this was hardly compatible with syphilitic causation. He also thought that employment must have something to do with its causation.

Sir D. Duckworth thanked Dr. Drummond for his lucid paper. With regard to syphilitic contagion, he thought occupation must have something to do with it. It was common in the army and rare in the sailor. The incidence of syphilis would probably be equal by land and sea. Syphilis was one of the destroyers of the nervous system—plus heavy dress and strain. Sailors were alcoholic and syphilitic, certainly. Gairdner said that in autopsies of aneurism there was usually no other lesions to be found. Thirty-nine or forty would be the usual age of aneurism, which also favored the idea of syphilis.

Dr. Valentine had been thirty years in India, and had made inquiries concerning syphilis. He had not seen twelve cases of thoracic aneurism, although there was a great deal of syphilis among his patients.

Dr. Ord said he was much interested in the palsy of the laryngeal nerve. Loss of phonation took place when the paralyzed cord fell back. Syphilis, he thought, took a very prominent part in the history of this disease. Iodide of potassium was a good palliative. Ergot of rye, it was thought, might cause contraction of the vessel. It came out quite clearly that the bulk of the aneurism, after taking ergot, was diminished. He gave twenty drops of liquid extract, and in twenty minutes the effect was produced by a diminution of blood-pressure.

The Cool Bath in Typhoid Fever.—Dr. Redmond read a paper on the cool-bath treatment of enteric fever. Dr. Currie, of Liverpool, had first of all introduced it. It was a prophylactic, rather than a curative, agent. The great danger in typhoid was pyrexia. The bath brought down temperature one to four degrees. Many patients (said Broadbent) recovered if cool baths were used at the onset of the disease. Dr. Taylor gave good evidence also, as also Trousseau. He advises all persons to try it in difficult cases. Dr. F. W. Hare had published 1,175 consecutive cases. In 1889 he said the clinical evidence in its favor was overwhelming. Dr. Cayley also gave evidences in its favor. Dr. S. Coupland was the last who had written in favor of it. When 102° F. is reached it should at once be used, if there was no hemorrhage. A bath of ten or fifteen minutes should be given, and repeated frequently. In some cases a tepid bath at 87° F., as long as the patient could bear it. A warm or tepid bath morning and evening was excellent practice. The bath first diminished the fever, the patient slept in the bath, and stupor disappeared, and he took cognizance of what was going on around him. Dr. Hare had only sixty per cent. of delirium. Sordes of the lips was rarely seen. A distinct diuretic action was made on the kidney. The statistics of expectation were not so good. In Germany 400 cases had been treated without one fatality. Brand had given bath statistics, three to four per cent. In England these statements had not been accepted. Dr. Hare's statistics confirmed those of Brand. He said 7.48 per cent. was the mortality in baths, and fourteen in expectation. Baths prevented pneumonia and typhoid symptoms. The labors and expenses was the great difficulty. Some patients and the general public had a great dread of baths. As to contra-indications, there was peritonitis and albuminuria. There was no other contra-indication. He, the writer, gave only four cases. Dr. Barr kept his patients continuously in the bath of 96° if the temperature was over 100° F.

Dr. Orr much approved of the cool-bath practice, and had been accustomed to put the patient into a bath of 90°. Was rather of the opinion that it was not merely a way of extracting heat. A corpse was found much less affected than a living body. It soothed the nerves which caused the hyperpyrexia.

Third Day, Friday, August 4th.

Dr. W. Ord, President of Section, in the Chair.

Railway Spine.—Dr. Byron Bramwell, of Edinburgh, opened a discussion on "Concussion of the Spine." He proceeded to read an abstract of the paper. There had been a great discussion as to the frequency of this lesion. These differences were too often argued out in our law courts. In the first place. the term concussion of the spinal cord must be clearly defined. A man in a railway collision, among many other symptoms, might suffer from pain in the back. In many such cases there was no concussion of the spinal cord. In the case of a hunter who fell off his horse, there was much pain in the spine, but no clear nervous symptom. It was therefore important to distinguish between concussion of the spine and cord. There were cases in which there was dislocation of the vertebræ. In some there was a hemorrhage into the cord. In some cases undoubted symptoms of organic disease of the cord followed. He had seen cases of undoubted pachymeningitis, locomotor ataxia, etc., which he was convinced had been caused by blows on the back or buttocks. After a railway accident we would naturally expect to have a certain number of such cases. True concussion of the spinal cord was common among colliers, from fall of coal on the back, or even fracture of the spine. Such patients either died or remained partially paralyzed. The retention of the urine lasted, after railway accidents, for some days or weeks. Such cases were common in colliery practice. Concussion of the spinal cord should apparently lead to organic disease; but such was very rarely the case. The tendency of modern legislation was to compensate persons for injuries which did not arise from their own carelessness; and doubtless such cases would soon become far more prevalent than they are at present. In many cases of railway accidents, the symptoms were rather cerebral than spinal. The symptoms were also rather subjective than objective. Changes in the fundus oculi were said to occur after railway accidents. The optic disk was said sometimes to be altered in appearance. In his experience this did not occur. Guards of railways rarely suffered from such diseases, and they were not found in persons who were severely injured. Many such patients recovered very slowly indeed. Sometimes there was permanent injury. It had been said that railway acci-

dents occasionally called forth myelitis or meningitis. He thought the symptoms were rather functional, and of the nature of hysteria or neurasthenia. Chronic spinal meningitis was uncommon in civil practice after injuries, and the diagnosis was very difficult in such cases. This rarely occurred in pitmen after accidents. Chronic cerebro spinal meningitis was a very rare disease. All admitted that spinal meningitis was often associated with cerebral meningitis. Electricity was a valuable assistance in diagnosis; but there were few cases in which it gave any positive results.

Dr. Brookhouse said it had occurred to him that the term spinal concussion was misleading. The simulation of symptoms of concussion was very simple. Concussion of the cord might cause either slight or severe symptoms. In cerebral cases it was possible to come to a conclusion; but in spinal cases it was nothing of the kind, as the symptoms were chiefly subjective. One patient got thinner, he had irregularity of the pupils, impaired hearing—this was a most uncertain symptom. Incontinence of urine coming on late in the case. Spinal tenderness. Urine of low specific gravity. The above symptoms were all subjective. On examination of his eyes the patient was so confused that it was clear the gentleman was cheating him. Dr. Brookhouse gave a very hostile report. For more than twenty years he had been medical officer of one of the largest railways. This patient was a rogue.

Dr. Alexander Robertson said that in a prognostic point of view, the existence of a given case of ankle-clonus was no sign of danger as to the utility of the limb. One patient who had a degree of ankle-clonus had walked sixty miles in one day. Hence the presence of these symptoms did not much damage the patient. A gentleman with absence of knee-jerk had just walked ten miles. Each case should be treated as a whole, no one symptom should be relied upon, and caution should be taken not to form too gloomy a prognosis on such cases.

Mr. Purey had been acting in Liverpool for twenty-five years for the Northwestern Railway. During that time he had only seen one case of death from injury to the spinal cord after a railway accident. This patient, a gentleman, was also tuberculous. About six months after he was perfectly paraplegic. He concluded that there had been some slight hemorrhage into the cord.

Dr. Bramwell justly was sceptical as to the existence of concussion of the cord. Probably hemorrhage was the real cause of such symptoms when it did occur. Ten years ago he had seen traumatic hysteria in a man who was supposed to have concussion of the spine.

Professor Clifford Allbutt said that in Leeds there had been a great number of railway accidents. Did not understand the meaning of concussion of the spine. Chronic muscular atrophy sometimes occurred. Next were cases of hysteria, and lastly ninety-nine of one hundred of the cases were nonsensical. Medical men connected with railways ought to go into the witness-box. Electricity was a most uncertain method of investigation. It was much against the medical man in court. He regarded atrophic condition of the optic nerve as possible, but it must not be made too much of. Hysteria was as bad a disease as any he knew.

Dr. Buzzard said that in ordinary accidents there was some hemorrhage. In no railway accident had he seen sclerosis of the cord. There was so much simulation in railway cases that he had declined seeing them. A patient complained of loss of sensation of one side. This really existed. The patient had some muscular atrophy and loss of knee-jerk. He had never seen optic atrophy after a railway accident. He had seen a case of catarrh after a blow on the head. Electrical tests were very untrustworthy and difficult.

Dr. Gordon thought that railway companies would do well if they would furnish a verbatim account of the trial. All medical men in court would do well to speak in court as they would in a medical society.

Dr. William Walker had had some experience in railway accidents. He had always appeared for his patients, and had found that in almost every railway accidents there were subjective symptoms. His present belief was that we must be very careful in accepting the statements of the patients. Out of his twenty all recovered. A medical officer of the Caledonian Railway had agreed that there were very few cases of gravity. Shock did a good deal of harm in some cases.

Dr. Saundby had been consulted by the railway companies, and had seen a certain number of such cases. Concussion of the spine was not a good title for the commencement of the discussion. A woman had anæsthesia of one side of the body. He referred to the difficulty of medical evidence. Dr. Gordon had truly said that the medical man in court should speak as if he was speaking before his medical contemporaries. His opinion was that railway companies did not at all try to bias the practitioners. One or two persons had died after railway accidents. He doubted that patients ever died after railway shocks. He had never met with muscular atrophy in such cases. He never employed electricity. Had never seen any change in the fundus oculi. He thought examinations of the patients should be brief.

Mr. Noble Smith had had many cases of accidents occurring to the spine, and had rarely seen such in railway accidents. In none of the cases he treated had there been death. Railway accidents were more sudden than others. A nobleman was thrown off his horse and had a shock on his feet. There seemed to have been slight dislocation in this case of the lower vertebræ. In a railway accident, after the shock, continuing the journey might do harm. Some cruel cases occurred where there had been protrusion of the vertebræ, and the patient was said to be merely hysterical. He cited such a case in a lady.

Dr. Eddison thought it hard that concussion of the spine should be objected to in the title of this paper. The real secret of the rarity of such accidents now was the invention of brakes. He had been in the Childwick accident. He had not been very ill after it, but had been affected. There were cases when a man gets tired and ill. The name concussion was not a bad one. Concussion was a shock carried to the nerve-cells. He did not see that railway companies had a right to make people hysterical.

Dr. Barnes had been spending the day in Edinburgh, and was in a severe accident near Lockerby. He felt much shaken after the accident. He became extremely emotional. He could not remember his friend's name, and used wrong names. He had no physical injury, but since then he had been well. There was in this case a shock of the brain from concussion.

Dr. Byron Bramwell said he admitted the term concussion of the spine was a wrong one, and this he agreed with. He had been anxious to let the lawyers know what they were talking about. Mr. Erichsen's work used the title concussion of the spine. The result of the discussion had shown that a certain amount of agreement existed among all persons of experience in this matter.

Dr. Clifford Allbutt moved that this Section recommend to the profession that, in all cases of disputed actions in court, it was expedient that the medical men on both sides should consult together before giving their evidence. This resolution was put to the meeting and accepted. A vote of thanks to Dr. Ord for his attention to the affairs of the Medical Section was proposed by Dr. C. R. Drysdale, seconded by Dr. Eddison, and carried by acclamation, and the President gratefully acknowledged the compliment. The meeting then adjourned.

SECTION OF OBSTETRICS, MEDICINE, AND GYNECOLOGY.

First Day, Wednesday, August 2d.

President's Address.—Dr. Murphy (President), in the course of a short introductory address, said that the three matters of greatest importance in obstetrics were: Ob-

struction of labor from position of child or narrowing of pelvis; post-partum hemorrhages; puerperal convulsions.

As regarded convulsions, he considered the best treatment to be the administration of chloroform followed by rapid emptying of the uterus; but even this left much to be desired. In the treatment of post-partum hemorrhage he considered that most reliance should be placed on pressure of the uterus by the hand. The mortality of placenta prævia had been much reduced, and in his own hands had been four per cent.; the treatment he adopted being to bring on premature labor, and not leave the patient until delivery was complete. In slight narrowing of the pelvis he preferred Tarnier's axis traction forceps to any other.

He considered that with the introduction of symphyseotomy and the reduction of the mortality of Porro's operation and Cæsarean section, the performance of craniotomy on the living child should never be required. He referred to the operative treatment of cancer and the importance of diagnosing it in the earlier stages, and said that in his opinion little reliance could be placed on the microscope as an aid in diagnosis.

As regards the treatment of fibroid tumors, he noted that in this country they were usually treated through an abdominal incision, but in France through the vagina by "morcellement." The discussion as to the relative value of the intra- and extra-peritoneal methods of treating the pedicle was still going on, but the balance of opinion seemed to be in favor of intra-peritoneal treatment. He thought that there was a tendency to neglect the minor gynecological operations, the most important of which he considered to be curetting, trachelorraphy, and perineorraphy. Curetting should be done thoroughly, the cervix having been previously dilated, and at the same time lacerations of the os should often be treated by trachelorraphy. For ruptures of the perineum he considered the flap-splitting operation by Tait's method by far the best.

Treatment of Diseases of the Uterine Appendages.—Dr Pozzi, of Paris, in opening a discussion on the "Conservative Treatment of Diseases of the Uterine Appendages," said treatment of the uterine mucous membrane was sometimes necessary in the early stages of disease of the appendages. This might be carried out, (*a*) by curetting, (*b*) cautery, (*c*) electricity in diseases of the uterine appendages. Massage was useful in a few chronic cases, but dangerous in cystic salpingitis and acute salpingitis. Electric currents only were applicable to chronic cases and acted principally on the neuralgic manifestations; used weak currents only. The operation of incising and evacuating cystic tubes was dangerous and not to be advised, because the tubes would fill up again. Conservative operations were most applicable to the ovaries.

The evolution of surgery tended to conservatism. Partial operations have been principally advised that fecundity might be preserved. They might be carried out when (*a*) there was disease of tube with ovary intact; (*b*) disease of ovary with tube intact. (*a*) Treated by salpingostomy; (*b*) treated by resection of ovary.

He had no faith in operations which aimed at restoring the function of the Fallopian tube, as he considered that the tube, when once it had been attacked by inflammation, would never resume its functions, because it was not a milk duct, and the exercise of its function depended on its contractile fibres and ciliated epithelium remaining healthy. He would eliminate partial resection of tubes from the conservative operations; he would practise and limit conservative surgery to the ovary only. He had found that partial resection of the ovary did not interfere with either menstruation or fertility. As a general rule, when the tube was healthy and the ovary injured he endeavored to preserve the healthy part of the ovary.

A typical case for this operation was an isolated dermoid cyst. The permeability of the tube must be proved by passing a stylet down from the abdominal end to the uterus. In cases in which the tube was likely to form adhesions he sutured the fimbriated extremity to the ovary—an operation which he would call salpingorraphy.

He has performed resection of the ovary six times, and ignipuncture of multiple small ovarian cysts in eight cases; all the patients recovered easily and were relieved by the operation; the menstrual flux has returned in each case, and one has subsequently become pregnant. The principal symptom before the operation was pain, worse at the period, and this has disappeared. In three cases he had performed hysteropexy; in addition, in five out of the six cases he had completely removed the appendages on one side, and resected the ovary on the other.

Dr. More Madden, of Dublin, thought it possible to pass a catheter from the uterus along the Fallopian tube, and so relieve a distention of the tube, and was accustomed to treat accumulations in the tube by tapping per rectum.

Dr. Sloan, of Glasgow, acknowledged himself a gynecological physician, and thought that the pendulum was now swinging back toward the medical treatment of many cases of disease of the appendages. Surgery or medicine in these cases was largely a question of diagnosis, and he thought that the surgeons troubled too little about diagnosis; but medical treatment if applied should be thoroughly carried out, which it frequently was not.

Dr. Fancourt Barnes, of London, said that catheterization of the tubes could not be carried out, as one could never be certain that the catheter had passed into the tube; he pointed to the impossibility in many cases of making a diagnosis before the abdomen was opened.

It was not always possible to remove the appendages after opening the abdomen, but he had seen good results from breaking down adhesions with the finger where removal was impossible.

Dr. Bell, of Glasgow, advocated curetting in many of these cases and ichthyol tampons. And in cases where operation became necessary would remove both ovaries completely.

Dr. Smyly, of Dublin, thought that diagnosis was not sufficiently studied, and that the treatment of early cases by curetting the uterus was good. Massage was good in cases of adhesions, especially Schultz's method without opening abdomen. It was difficult to tell what was healthy and what unhealthy, even when between the fingers; but healthy tissue should always be left.

Dr. Aust Lawrence, of Bristol, dwelt on the difficulty of diagnosis in cases of disease of the appendages, but if fluid was present would open the abdomen. He found the faradic current do good, urged the importance of rest in bed, and the impossibility of carrying out proper non-operative treatment in the poor.

Dr. Murdoch Cameron, of Glasgow, had found faradic current invaluable in cases of chronic ovaritis. He was opposed to resection of the tube and to removal of the sound ovary in oophorectomy, had no faith in the possibility of passing a catheter along the Fallopian tube.

Dr. Brewis, of Edinburgh, urged the impossibility of diagnosing the condition of the appendages before opening the abdomen. He thought tapping cysts per rectum bad treatment.

Mr. John W. Taylor, F.R.C.S., of Birmingham, noted that Dr. Pozzi had performed hysteropexy in some of the cases, and questioned how far that had produced the good effect by lifting up the ovary from its prolapsed position. He had found curetting sometimes dangerous, and had seen cases followed by pyosalpinx; in these cases there was probably some antecedent gonorrhœal salpingitis; as an example of conservative surgery he mentioned the enucleation and removal of a broad ligament cyst without interfering with ovary or tube, which he had often practised.

Dr. Cullingworth, of London, considered all conservative operations on the tubes as utterly useless, but when applied to the ovaries they were useful, as it was important, if possible, to preserve some ovarian tissue. He thought the sentimental reason a strong one, as a woman, especially if young, who was not menstruating

was apt to consider herself as unlike other women. He asked Dr. Pozzi whether he considered that small cysts studded over the ovary needed treatment. He considered the proposal to suture the fimbriated extremity of tube to ovary a valuable one.

Sir Spencer Wells (Bart.), of London, said, where one ovary was sound he would remove the whole of the diseased one. He considered tapping per rectum bad, and thought that all had seen cases in which removal of the appendages had been advised by gynecologists, and yet, although the operation had never been performed, the patients had got quite well. He asked Dr. Pozzi how far he considered that one might leave ovaries studded with small cysts, which he regarded as Graafian follicles; he had often left them after puncturing them, with good results.

Dr. Heywood Smith, of London, considered that the prognosis and treatment advised must differ in the rich and the poor. When one ovary was diseased he would remove both. He thought that treatment by faradic current gave temporary relief only.

Professor Pozzi, in reply, considered catheterization of Fallopian tubes usually impossible and always dangerous, and tapping per rectum very dangerous. Opening the abdomen was always a grave operation, and one not to be undertaken lightly. He thought when adhesions had been separated they were very apt to form again, and considered a weak current of electricity good for neuralgic pains, but that it could not cause absorption of effusions. He had known curetting in acute cases to be the cause of a pyosalpinx, and thought fingers much more important than eyes in detecting disease of ovaries after opening abdomen. One could feel small cysts even when in interior of ovary. Laparotomy was hardly ever necessary in cases where there were no physical signs, but sometimes it had to be done on the indication of symptoms only.

On the motion of Sir Spencer Wells, seconded by Dr. Robert Barnes, a hearty vote of thanks was passed to Professor Pozzi with acclamation.

Lithotomy in Women.—Dr. Fancourt Barnes, of London, then read a paper on "A Case of Lithotomy in the Female Bladder." Of the three methods available in the treatment of vesical calculus in the female, viz., supra pubic or vaginal lithotomy, or dilatation of the urethra, he preferred vaginal incision. Dilatation of the urethra may be followed by incontinence of urine, which is a condition defying treatment. After vaginal incision a fistula sometimes follows, but this may be cured by a subsequent operation.

Dr. Aust Lawrence had operated on three cases by the vaginal method. He considered that if the urethra was incised instead of dilated, there was less liability to subsequent incontinence.

Dr. Purslow, of Birmingham, read a paper on "The Treatment of Retroversion of the Gravid Uterus." After referring to the literature of the subject, he narrated six cases which had come under his treatment at the Queen's Hospital, Birmingham, in the last twelve months, and urged strongly the advantage of the genu-pectoral position over the administration of chloroform, and the importance of avoiding hasty endeavors to procure replacement.

Dr. Heywood Smith agreed as to the importance of avoiding chloroform if possible, as without an anæsthetic there was much less liability to use too great violence, as the amount of pain was an indication of what might be safely used.

Dr. Aust Lawrence also agreed in the avoidance of haste. Practically the only danger lay in the distention of the bladder, and if this was emptied regularly little harm resulted.

(To be continued)

An Epidemic of Suicide has prevailed in Buda-Pesth and other Hungarian towns lately. In Buda-Pesth alone seven suicides occurred in one day a few weeks ago. The number of cases of insanity is also said to be increasing so rapidly that the hospitals and asylums are crowded.

Correspondence.

MEDICAL STUDY IN EDINBURGH.

To the Editor of the Medical Record

Sir: It occurred to me that many of your readers would be interested to know something of the opportunities for post-graduate study afforded during the spring and summer months in Edinburgh.

The practising physician residing in New York, or any of our large cities, finds his time during the greater part of the year so entirely consumed by the demands of private and hospital practice, that little or no opportunity occurs for reviewing favorite subjects or pursuing studies which do not come within the immediate compass of his special line of work. The necessity for occasional review and study is, I believe, experienced by all who would keep abreast of the times and who wish to continue to be familiar with the constant advance of science. This work, therefore, must be undertaken during the vacation, which it is very generally the custom of the physician to take during the summer, and although our own post-graduate schools offer now as good, if not better, facilities than many of the medical centres of the Old World, still the excessive heat during the summer months prevents many from availing themselves of the opportunities offered at home.

This is especially true if one wishes to pursue the study of anatomy, and it was this circumstance which induced the writer to visit the city of Edinburgh; which, in addition to its opportunities for scientific study, offers as a further inducement, a delightfully cool summer climate, many points of historic interest both in and about the city, and an easy access to the magnificent scenery of the Scottish Highlands

Edinburgh has long been noted for its medical schools. The medical department of the University of Edinburgh, founded in 1705, has, ever since that time enjoyed the reputation of being one of the most thorough and practical institutions for medical education in the United Kingdom.

The Edinburgh School of Medicine and Surgery is even older than the University, and has long maintained an excellent standard of medical teaching. Between these two schools there exists a friendly and healthy rivalry, which conduces to the maintenance of the high standard of each.

The summer sessions begin about May 1st and continue until the last of July. During this time many excellent practical courses are given by the different instructors, which can, with much profit, be taken by visiting students or graduates. The Royal Infirmary, one of the largest and best-equipped hospitals in Great Britain, is situated on Lauriston Place, immediately opposite the University buildings. It is built on the pavilion plan and is divided into eight blocks containing thirty-four large wards. Of these eighteen are for surgical and twelve for medical patients; two are devoted to venereal cases, and one is reserved for laparotomies. There are also recently added wards for patients suffering from diseases of the eye, ear, throat, and skin.

The consulting and visiting staff of this institution is composed of forty-five of Edinburgh's most distinguished men, including, on the medical side, Professor Grainger Stewart, Professor Alexander R. Simpson, Drs. John Wyllie, Andrew Smart, and Alexander James. Among the list of surgeons are found the names of Mr. John Bell, Mr. John Chiene, Mr. Thomas Annandale, and Mr. John Duncan.

It has been my privilege during the past month to attend many of the clinics and diagnosis classes given at the Infirmary by different members of the two medical faculties, and I have been most favorably impressed with the painstaking, care, and apparent enthusiasm with which the instructors demonstrate and impress upon the students the salient points to be remembered in each individual case.

This is especially true in the medical department, where the student is constantly referred to his knowledge of anatomy, physiology, and pathology, so admirably taught in other departments of the University, and the practical application shown.

I was especially fortunate in being able frequently to attend the diagnosis class conducted by Dr. Alexander James, which is deservedly popular among the students of both schools. His method of teaching is clear, forcible, and thorough. An hour is frequently consumed in the examination of a single case; but the time is well employed, and no student or practitioner who is fortunate enough to be present leaves without some new idea or useful suggestion.

Owing to the immense amount of material furnished by the Infirmary, the instruction in clinical surgery is never lacking in illustration. The chair in surgery in the University is held by Mr. John Chiene, whose success as a teacher and skill as an operator have won for him a high rank in the estimation of the medical fraternity.

It is a lamentable fact, however, that with one, or possibly two exceptions, the surgeons of Edinburgh utterly fail to appreciate the advantages to be gained by the application of the modern aseptic and antiseptic methods of wound treatment now so generally practised by surgeons throughout the civilized world; or if they appreciate the advantages, fail to give their patients the benefit of them. It is true that they employ antiseptic solutions for cleansing the wounds, and occasionally a part is scrubbed before operation. The surgeon usually washes his hands, and as frequently wipes them on any towel which happens to be near. The assistants rarely take this precaution, and the nurses never (in public).

I witnessed a shoulder-joint amputation before the class by Edinburgh's most distinguished professor of clinical surgery. Neither the surgeon nor any of his assistants wore anything other than their ordinary garments. The hands may have been disinfected before the operation, but certainly nothing further was done during this or the following operation to overcome the contamination necessarily incident to the free handling of soiled towels, wooden chairs, tables, instrument-cases, woollen blankets, and various other articles about the amphitheatre and contained in the pockets of the operator and his assistants.

In the midst of the operation the surgeon takes a spectacle-case from his coat-pocket, removes his glasses, places them in position, and resumes his work without even immersing his fingers in any of the antiseptic solutions which are everywhere present. The drainage-tube which is employed is passed through at least two pairs of septic fingers, and has been in contact with the hair and coat-collar of the operator. These are but a few of the many sources of infection which I noticed in one short operation, and I believe it to be a fair example of most of the surgery to be seen at the Infirmary.

On one occasion, however, I was much encouraged by seeing an operator and his house-surgeon in clean linen gowns, with sleeves rolled up, and with apparently clean hands. The operation was for the removal of a foreign body from the knee-joint, and as the patient's leg had been thoroughly scrubbed and was surrounded by towels wet in some antiseptic solution, it seemed that the operation was to be conducted as such operations are in our own hospitals by our own careful surgeons. About the middle of the operation, however, the assistant whose duty it was to look after the instruments and prepare the ligatures and sutures, came into the amphitheatre with a crowd of students from above, descended the stairs, jumped over the rail into the arena, and immediately began to perform his duties without washing his hands, or even dipping them into a solution which was easily within reach. The surgeon called for a gut suture to unite the capsule of the joint before closing the wound. The young man threaded a needle, and not at once finding a pair of scissors to cut the gut, plunged his hands into a pocket, withdrew a pair of scissors, divided the suture, and then, as if to remove any possibility of its remaining clean, drew its whole length between his more than septic thumb and forefinger. That suture, and many others prepared in the same manner were used, and that without a word of censure from the surgeon, who was obliged to witness all while he waited for the needle. The dressing which was placed next the wound was handled by two nurses, neither of whom had taken the slightest precaution to disinfect their hands.

It indeed seems strange that in one of the greatest medical centres of Great Britain, where medical education is supposed to be on a plane far above that of most nations, and at a time when the knowledge of the methods employed in the practice of aseptic and antiseptic surgery is so generally disseminated, that such examples of gross carelessness should be constantly before the eyes of the thousands of students who annually seek in Edinburgh the instruction which is to qualify them to practise the healing art.

In fairness it should be said that in the writer's opinion the above is the only point in the system of medical instruction at the University of Edinburgh that can be justly criticised; the theoretical instruction is excellent, and the opportunities for individual laboratory work in chemistry, physiology, histology, and pathology leave little to be desired.

The department, however, which has contributed most to the reputation of the University is undoubtedly that of anatomy. This is due both to the excellent system of teaching and to the skill of the individual instructors.

For nearly thirty years the department has been under the immediate charge of that distinguished scholar and able anatomist, Sir William Turner, whose well-known contributions to the literature of the subject have gained for him a place in the foremost rank of the world's authorities.

Dr. David Hepburn, the senior demonstrator, to whom much of the personal instruction is entrusted, possesses a rare gift in his ability to impart the knowledge of dry and uninteresting anatomical facts in a manner which interests the student, and at the same time fixes the fact firmly in his memory.

In his daily demonstrations he employs recent dissections and black-board drawing. In the latter he is particularly clever, and with a few colored crayons is able to reproduce the anatomical picture, which is often too indistinctly seen in the dissection, with a distinctness and accuracy of detail which renders it strikingly clear.

As a substantial aid to dissectors, the University has a wonderfully fine collection of carefully dissected parts, embedded in cement, preserved in alcohol, and contained in hermetically sealed glass-cases These are conveniently arranged on a gallery in the dissecting-room, with explanatory diagrams. The collection numbers nearly one hundred dissections, and illustrates in the best possible manner the appearances which a well-conducted and careful dissection should reveal.

It is because my brief stay in Edinburgh has been so enjoyable that I venture to send these lines to your journal in the hope that they may meet the eyes of others who are desirous of passing their vacation in the same way. If one has two or more months at his disposal I know of no city in which a medical man can pass a more delightful or profitable season. It is a pleasure also to record with what marked kindness and courtesy a foreigner is treated by all connected with the medical schools or hospitals.

Very truly,

GEORGE EMERSON BREWER.

EDINBURGH, SCOTLAND, July 22, 1893.

The University of Wales.—The Charter of the University of Wales has been published and has been laid before Parliament. Degrees are to be given in arts, science, law, and music; but the Charter confers no power to admit to any degree in medicine or surgery.

ELECTROCUTION.

To the Editor of the Medical Record.

Sir: Horrible as are the accounts detailed in the newspapers of this country of the lynchings, murders, homicides, and suicides that seem daily to occur, none, to my mind, are so revolting as those lately given of the electrocution of a murderer in Auburn State Prison.

Science is said to be the handmaid of progress, but when applied, or rather misapplied, to the execution of criminals, I hold that it is degraded from its high position and is made, by the publication of its horrid details, a means of pandering to morbid curiosity, and leads to the demoralization of the masses.

The death penalty is meant to be deterrent and punitive, but not to be the means of suffering to the criminal. Electrocution it was thought would secure these ends, but evidently it has not done so. It has not prevented crime, and can scarcely be said to have punished it when the victim is made the subject of pity and becomes almost a hero by his sufferings; and it has not been more certain, or more swift, or humane in its ghastly service than the means generally made use of in the other States of this great Union and in other countries.

When an individual has outraged humanity from motives of jealousy or revenge, no punishment that he may receive will deter others from committing a similar offence, and he is not punished by death, for fear of his own death does not enter into his calculations at all, indeed in most cases he attempts to take, and often succeeds in taking, his own life. For such persons imprisonment for life is a life-long punishment, and gives time for reflection and repentance; but when a man or woman commits murder as a sequence to the lust of the eye or of the flesh, when, as often occurs, it is committed while the victims are asleep or in the dead of night, in order to obtain possession of their goods, or they daily poison friends and relatives for the sake of their money, or he murders his violated victim, I think that electrocution or the guillotine is too refined a punishment. The murderer has committed a cold-blooded crime, he has had time to reflect on the consequences of his act and has deliberately chosen his part, and should be made, after a certain time given him for reflection, to expiate his offence by a disgraceful death. Like a brute he has lived and like a brute should he die—not in an elegant chair surrounded by men of science and literature, but on the gallows, in silence and obscurity. Such a punishment may act as a deterrent, not the glorification of an electrocution.

That the punishment of death may, with due precaution, be carried into effect by hanging, is a fact within my own experience; for some years ago I had, as surgeon to a gaol, to attend on and witness the execution of a Hindoo, who had in a fit of jealousy murdered his paramour. He had, immediately after killing her, cut his own throat, or rather trachea, which wound had not healed when he came under my care. I attempted to close it before his execution, but found that through long disuse of his larynx the closure of the wound so nearly caused asphyxia that I was obliged to desist. Time pressed, and notwithstanding my appeal for more time to the authorities, the execution was ordered to take place immediately, so that he was led to the scaffold still breathing through the aperture. He was a thin, wasted man, weighing only about one hundred and twenty pounds, but his death was immediate, and on dissection I found that the odontoid process of the atlas was fractured and pressed on the medulla. He died free from pain, and as scientifically as any one could desire.

Let the rope be applied by a skilled executioner, with half the precautions necessary in electrocutions, and the murderer will meet his doom. He will die the death of a brute, but not brutally, and the published verdict of a coroner's jury will be sufficient to assure the public that the majesty of the law has been vindicated. In the name of science and in the cause of humanity I, as a stranger and an admirer of your country and its institutions, plead that this electrocution be abolished; but if the Gerry law is like that of the Medes and Persians, let due care be taken that it should be executed under the supervision of medical electro experts, and with a perfect apparatus, so that no more such painful and demoralizing scenes may again occur.

I am, sir, yours sincerely,

James Cecil Phillippo, M.D.

Jamaica, W. I.

THE RECRUDESCENCE OF LEPROSY AND ITS CAUSATION.

To the Editor of the Medical Record.

Sir: I am indebted to your courtesy for a copy of the Medical Record containing a notice of my recent volume on leprosy and vaccination. Your critic takes me to task pretty severely for daring to question the utility and safety of vaccination, and, while admitting that reliance may be placed upon the facts I have for the first time brought together, characterizes my volume as "one of the most curious freaks of modern times," and is of opinion that my conclusions "are not to be trusted in the slightest degree." As the readers of the Medical Record would scarcely comprehend the scope and purport of my volume from your brief review, I shall be glad if you will kindly allow me a short space to state what these are. As the facts and statistics showing the serious increase and wide distribution of leprosy are allowed by your critic to be reliable, I will merely quote one authority on this part of my case, that of the late Sir Morell Mackenzie, who said in an article entitled "The Dreadful Revival of Leprosy," which appeared in the *Nineteenth Century* for December, 1889, after referring to its diffusion in Europe and America: "In almost every other quarter of the globe leprosy is rife at present, and wherever it exists it seems to be slowly but surely extending its ravages. It is impossible to estimate even approximately the total number of lepers now dying by inches throughout the world, but it is certain they must be counted by millions. It cannot be comforting to the pride of England—the august Mother of Nations—to reflect that a very large portion of these wretched sufferers is to be found amongst her own subjects."

To the question of causation I have devoted my chief attention, and besides communicating with superintendents of leper asylums, eminent dermatologists, and others, I have made personal inquiries where leprosy prevails in all parts of the world. I have carefully examined the evidence for all the alleged factors, such as heredity, contagion, insanitation, syphilitic cachexia, a fish diet, malaria, etc., and have quoted what the most eminent authorities have to say thereupon. All these factors, allow me to observe, have been in existence for centuries, and do not account for the recent alarming recrudescence of the disease. Upon each of them there is considerable divergence of medical opinion, as I have shown. What one authority affirms, another denies, and the investigator, however patient he may be, is left in a state of hopeless bewilderment. There is, however, one cause upon which, in all the countries I have visited, there is no such confusion, but a nearly unanimous consensus of intelligent opinion—I mean inoculation. About forty pages of testimonies and experiences are given under this head, which include those of the leading medical journals and some of the most eminent pathologists, lepra specialists, and hospital physicians in all countries. As accidental inoculation is not of sufficient frequency to account for so large a development of the disease, it follows that there must be some other cause, and that of an innovating character or a comparatively new departure. This cause, I maintain, is vaccination, which is the only form of inoculation generally practised, and meets the case at all points.

Vaccination is admitted, though with reluctance and sometimes with apology by the highest authorities, to be

capable of transmitting and aiding the ravages of this much-dreaded disease. The authorities on this part of my case include Sir Erasmus Wilson, the father of dermatologists; Dr. John D. Hillis, formerly Superintendent of the Leper Asylum, British Guiana; Dr. Liveing, Sir Ranald Martin, Professor W. T. Gardner, of Glasgow; Dr. Tilbury Fox, Sir Gavin Milroy, Dr. R. H. Bakewell, formerly Vaccinator-General, Trinidad; Dr. A. S. Black, Trinidad; the eminent bacteriologist, Dr. Edward Arning, Hamburg; Professor H. G Piffard, New York; Dr. Walter Gibson, late President Board of Health, Hawaii; Dr. Blanc, Professor of Dermatology, New Orleans; Dr. Sidney Bourne Swift, late Medical Director Leper Settlement. Molokai, Hawaii; Dr. P. Hellat, St. Petersburg; Professor Henri Leloir, Lille; Surgeon Brunt, Dr. John Freeland, Government Medical Officer, Antigua; Dr. S. P. Impey, Superintendent Leper Settlement, Robben Island, Cape Colony; Dr. H. S. Orme, President State Board of Health, California, and many others.

For the first time there has been brought together some of the incriminating facts, comprising nearly one hundred pages of closely packed testimonies—nearly all medical—as to communication of leprosy by means of vaccination, and in addition I have given particulars of numerous cases of such communication, with chapter and verse, by the recording physicians.

The results of my investigations may be briefly summarized as follows:

1. That leprosy has greatly increased during the last half-century, and that it is prevalent in many places where it was formerly unknown.

2. That while the opinion of medical authorities and experts varies considerably on the subject of the contagiousness of leprosy, the preponderance of authority is in favor of the theory that it is not contagious in the ordinary sense of the term, but is communicable by means of a cut, sore, or abraded surface; and this view is confirmed by my own personal investigations.

3. That other alleged factors, such as malaria, a fish diet, syphilitic cachexia, heredity, and insanitation are admittedly unequal to explain the rapid growth of the disease in certain of our Crown colonies and dependencies, as well as in other countries.

4. That on one point there is much agreement, and hardly any dissent, namely, the inoculability of leprosy; and that the view of leprosy as an inoculable disease, while it is most clear to those who take the malady to be due to a bacillus, is older than the bacteriological evidence, and is not dependent thereon.

5. That the most frequent opportunities of inoculating the virus of leprosy are afforded in the practice of vaccine inoculation, which is the only inoculation that is habitual and imposed by law; and that the evidence here adduced is calculated to show that vaccination is a true cause of the diffusion of leprosy.

6. That the official information, collected by interrogatories and otherwise, has not been hitherto of a kind to show how far vaccination has determined the amount of leprosy in recent times; and that any interrogatories that may be sent out in future should not be limited to ascertaining the effects, as regards leprosy, of hypothetically "pure lymph." When on very rare occasions interrogatories have been submitted, they have been framed to ascertain the results of a purely hypothetical system of vaccination, which is not anywhere discoverable in practice (*i.e.*, with pure lymph and free from hereditary taint), and the replies are therefore futile and misleading.

7. That with the exception of two groups of cases—those adduced by Dr. Roger S. Chew, of Calcutta, and Dr. S. P. Impey, of Robben Island—those reported in this volume have not been the result of special investigations, but have cropped up accidentally in the course of medical practice, and in some instances have been published by practitioners with apologies to the profession for presenting such unwelcome disclosures.

8. That the increase of leprosy in the Sandwich Islands, the West Indies, the United States of Colombia, British Colombia, British Guiana, South Africa, and New Caledonia, has followed *pari passu* with the introduction and extension of vaccination, which in nearly all these places, without previous inquiry or demand from the inhabitants, has been made compulsory.

9. That as leprosy is a disease of slow incubation, often taking years to declare itself, and in its incipient stages can be detected only by practitioners of large experience, it follows that, in countries where leprosy exists, there is great danger of extending the disease by arm-to-arm vaccination.

10. Leprosy being one of the most loathsome diseases to which the human race is subject, and being practically incurable, it behooves all interested in the public well-being to do their best to prevent its diffusion, and, as a means thereto, to discourage the practice of vaccination on that ground, if on no other.

Trusting to your spirit of fairness for the insertion of this explanatory communication,

I am, yours faithfully,

WILLIAM TEBB.

DEVONSHIRE CLUB, ST. JAMES'S STREET, LONDON, S.W.,
July 29, 1893.

A NEW TREATMENT OF HÆMORRHOIDS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Dr. Becelaere, in his article on a new treatment for hæmorrhoids, published in the MEDICAL RECORD of July 29th, recommends covering the part to be operated upon with collodion as a preparation for ignipuncture. Collodion "thoroughly solidified" he considers "a most sufficient means of avoiding the disagreeable effects of radiating heat."

As solidified collodion is simply gun-cotton, it is clear that the writer has not sufficiently considered the consequences of covering the anal region with a layer of this substance and then piercing through it with the thermocautery.

A. H. S.

NEW YORK, August 4, 1893.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 19, 1893.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	29	4
Scarlet fever	37	5
Cerebro-spinal meningitis	2	2
Measles	111	6
Diphtheria	93	26
Small-pox	0	0
Cholera	0	0
Varciella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

A Mexican Remedy for Typhus Fever.—Recent reports from Mexico state that a remedy for typhus fever has been found in jicama (dolichos tuberosus), a plant cultivated to some extent in the tropical regions of America. So many recoveries from the disease under domestic treatment by this plant have been reported, and so great is the popular interest in its alleged virtues, that the Mexican Medical Institute has now appointed a special commission to study the remedy, which is to be subjected to microscopic examination and chemical analysis, and with which experiments are to be made upon typhus patients. Jicama (pronounced Hee'camah) is a valerianic plant, indigenous it is said to New Holland, which is cul-

tivated in Mexico and the West Indies on account of its popular reputation as a valuable remedy in diseases of the chest and scabies.

The Wily Patient and the Credulous Physician.—The Dublin correspondent of the *Hospital Gazette* says that an old Government official presented himself at the consulting-room of one of the local practitioners and was told, after examination, that his liver was enlarged, his heart weak, and that his kidneys were degenerated to an alarming extent. He was advised to settle his affairs, as his time was short. This he proceeded to do, and made over, like Captain Cuttle, to the kind physician a policy of life insurance and an order for a small pension soon to fall due, the only condition being that he would see his patient over the Styx, pay the ferryman, etc. The end came, and the doctor having paid the funeral ex penses, etc., armed himself with a copy of the certificate of death, and proceeded with the policy to the insurance office. Alas, it had been dead for years! Only one hope remained, the arrears of pension, but this the victim of liver and nephritic disease had commuted some twelve months previously.

The International Congress of Hygiene and Demography.—The Emperor of Austria has accepted the office of Protector of the International Congress of Hygiene and Demography, which will be held in Buda-Pesth in 1894. The organizing and executive committees have now been formed and are in full work. The Congress will consist of two divisions, hygiene and demography. The General Secretary is Dr. Koloman Müller.

Mr. Bland Sutton has recently been awarded the Jacksonian Prize of the Royal College of Surgeons.

The First Medical Journal in Brazil was the *Propagador das Sciencias Medicas*, established by Dr. J. F. Sigand, in 1827. It lived but a little over one year. Three years later, Dr. Sigand started the *Semanario de Sande Publica*, of which three volumes appeared. Since that time some forty journals have been born in the country, but nearly all of them were doomed to an early demise. *O Brazil Medico*, the leading journal of Rio de Janeiro, was founded by Dr. A. A. de Azevedo Sodré, in 1887.

Salicylic Acid for Coryza.—Dr. J. A. Wegg, of Spanish Town, Jamaica, writes to the *British Medical Journal* that he has found that natural salicylic acid used as an errhine is a reliable agent in arresting a fresh-cold coryza. He has used it in his own cases in London, the United States, and Jamaica with uniform success. A few grammes, say two or three, of the salt, dry, are placed into an ordinary paper pill-box, in the cover of which three small holes are bored. Shake up the contents immediately before snuffing, and continue doing so until sternutation is produced. The process is to be repeated according to circumstances or the amount of hyperæmia of the nasal mucous membrane.

A Medical Congress in the United States of Colombia.—A National Medical Congress will meet in Bogotà, United States of Colombia, on October 12, 1893. The sessions, which will be held under the presidency of Dr. José M. Buendia, will continue for ten days. The subjects on the programme include the matters of general pathological and clinical interest at present most in debate in the medical world, but local color will be given by discussions on the climate of the country, its mineral waters, the poisonous reptiles which infest it, the parasites indigenous to it, etc.

How Not to Learn Italian.—The pedagogic editor of *The Lancet* advises intending visitors to the International Congress to brush up their Italian by studying Dante's "Purgatorio," a literal translation of which has recently been brought out in London. One might as well learn English from Spenser, or modern Greek through a pony on the "Iliad."

BOOKS RECEIVED.

A Text-Book of Medicine. By Adolf Strümpell, M.D. Second American Edition, translated from the second and third German editions, and revised from the sixth German edition, by H. F. Vickery, M.D., and P. C. Knapp, M.D., with Notes by F. C. Shattuck, M.D. Royal 8vo, 1,043 pages, illustrated. Price, $6.00. D. Appleton & Co., New York.

Transactions of the Fourteenth Annual Meeting of the American Laryngological Association, held at the City of Boston, June, 20–22, 1892. 8vo, 121 pages, illustrated. D. Appleton & Co., New York.

On Snake-poison, Its Action and Its Antidote. By A. Mueller, M.D. 8vo, 85 pages. L. Bruck, Sidney, N. S. W.

Transactions of the Southern Surgical and Gynecological Association. Vol. V. Fifth Session, held at Louisville, Ky., November, 16–18, 1892. 8vo, 434 pages.

Transactions of the American Associations of Obstetricians and Gynecologists. Vol. V., for the year 1892. 8vo, 529 pages.

A REPORT ON TWENTY-THREE CASES OF INGROWING TOE-NAIL OPERATED UPON BY THE METHOD OF ANGER.[1]

BY CHARLES N. DOWD, M.D.,

NEW YORK.

ASSISTANT SURGEON TO THE NEW YORK CANCER HOSPITAL AND THE VANDERBILT CLINIC.

INGROWING toe-nail is an ailment which seldom calls for operation when the patient is intelligent and careful. If the nail is allowed to grow so long that its lateral margin does not plow into the side of the toe and irritate it, and if the patient will wear broad-toed shoes, and keep clean, there need seldom be any serious inconvenience.

Among the patients who frequent dispensaries, however, there is much suffering from this malady, and the pain and inconvenience are frequently sufficient to prevent them from attending to their ordinary duties. In such cases operation is generally the best method of effecting a cure.

During the last two years I have operated upon twenty-three such cases at the Vanderbilt Clinic, by the lateral flap operation of Anger, and as this particular operation has not been much done in New York, it has seemed well to report the cases.

The cures seem to be permanent, and healing is much more rapid than by the operations ordinarily done. The operation consists of the removal of the side of the ingrowing nail, the inflamed tissue about it, and a portion of the matrix, leaving a lateral flap which is applied over the raw surface.

The lines of the incision are shown in Fig. 1, *A*, *B*, *C*, *D*.

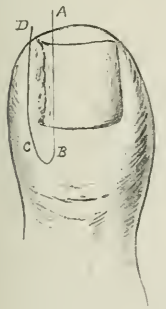

FIG. 1.—Showing Lines of Incision.

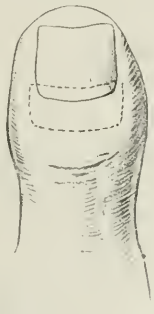

FIG. 2.—Dotted Lines Indicate Position of Matrix Proper.

The essential feature in the radical cure is the removal of that portion of the matrix from which the troublesome part of the nail grows. The matrix of the nail should be distinguished from the bed of the nail. The position of the matrix is indicated somewhat schematically by the dotted lines in Fig. 2.

When this is removed, the growth of the nail ceases.

Quenu[2] proved this by twisting off nails and then excising that portion of the subungual dermis which lay back of the lunula. No nail grew, only a few horny lamellæ from the anterior part—the bed of the nail—which was left intact.

In removing the matrix, it is important to cut well back. Sappey[1] states that "the subungual dermis arises at the place where the extensor tendon is attached to the third phalanx of the toe, and that it is intimately adherent with the periosteum of this phalanx." Since this tendon is inserted at the base of the phalanx, Quenu and Anger in their operations have removed the tissue nearly back to the joint.

Anger[2] scrapes the bone well, at least one-fourth inch back of the visible portion of the nail. Sometimes he removes a thin lamella of bone. In the cases which he reported he used ice and sea-salt as a local anæsthetic, and adjusted the flaps with strips of adhesive plaster. Under this technique he considered it necessary to keep his patients in bed for a week, and did not allow them to walk before the tenth or twelfth day.

In the cases which we are now reporting cocaine was used as a local anæsthetic, the flap was stitched in position, and the patients were not confined to bed at all, but were allowed to walk immediately. ℥ xx. to xxv. of a four per cent. solution of cocaine hydrochlorate injected into the skin sufficed to give good anæsthesia, so that the matrix could be carefully and leisurely dissected away. No lamella of bone was removed, but all the tissue which seemed like matrix was cut away with much care, the periosteum being scraped from the bone just at the base of the nail. This removal of the matrix was more thoroughly done in the later than in the earlier cases, and the later results were accordingly somewhat better.

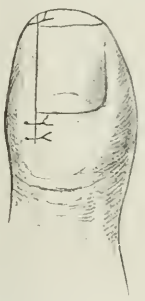

FIG. 3.—Flap and Stitches in Position. Dorsal Surface.

FIG. 4.—Flap and Stitches in Position. Plantar Surface.

A bit of rubber tubing tied about the toe prevented hemorrhage, and thus facilitated the dissecting out of the matrix; the slight hemorrhage which followed its removal was easily controlled by torsion and pressure.

The stitches, which were of horsehair, were applied as shown in Figs. 3 and 4.

A firm bandage of sterilized gauze was applied so as to bring considerable pressure on the flap; a gauze, cotton, and crinoline dressing was applied outside of this so as to envelop the entire foot. A rubber or old shoe was cut so as to admit this bulky dressing, and the patient was allowed to walk home or to the street car.

[2] Anger: Bull. et Mém. de la Société de Chirurgie de Paris, 1889, p. 594.

Careful aseptic and antiseptic precautions were employed.

The first dressing was ordinarily left on three to six days.

The advantage claimed for this simple operation is that healing is accomplished in less time than by the other operations which give as good results. Let us examine the records of these cases and see if the claim is substantiated.

The inflammation in all the cases was of a severe type, sufficient to seriously interfere with or prevent the patient's working. There was usually a history of acute inflammation for a month or two, with preceding irritation for a year or two.

Seventeen out of the 23 cases were seen five months or more after the operation. In 11 of these 17 cases, the period was over a year; and in 5 of those it was over a year and a half. Of the remaining 6 cases, 3 were seen six weeks after the operation, the others from twelve to twenty-six days. We are thus able to judge well of the results of the operation. In following these cases for this unusually long time, I have been greatly aided by Dr. A. Agramonte, who has been much interested in the operation and the results.

All of the cases when last seen were cured, with one exception. The history of this exceptional case is as follows:

On the day following the operation she had a fit on the street, presumably hystero-epilepsy, and was taken to a hospital in an ambulance. The dressing was there removed from her foot, and the stitches taken out. She was seen two weeks later, and then had a granulating rim at the line of incision. She came back to the clinic very irregularly, three or four times more, and then passed from observation before healing was complete. There is little doubt that she was really cured, although I am unable to definitely record such a result.

In the other cases which were seen later than five months, the cure was complete. When last seen there was no tenderness and no tendency to recurrence, and the toes looked normal, excepting that a thin line marked the site of previous incision.

We can thus feel confident of curing our patients by this operation. Anger reported one hundred and seventeen cases, and stated that he did not see a single relapse among them all.

Now let us turn to the other point. Is the cure effected more easily than by other methods? I will give the history of a good case to show what we may expect when all goes well, and then will group and make extracts from the histories of the others.

No. 10. Saleslady. Ingrowing nail two and a half years. Very severe symptoms two months. At present time the edge of nail grows deeply into the side of toe, and there is much granulation about it. Operation done August 6, 1891. The next day, August 7th, she came to clinic, stated that she had slept well, and that she walked about the house and to the street car with comparative comfort. Six days later, August 13th, the dressing was changed and healing by first intention was found. She stated she had walked about in comfort since the first day. The stitches were removed and she went directly from the clinic to her work as saleslady, with the toe protected by a gauze bandage.

She was seen four days later and was then dismissed from observation, "cured." She was seen a year and a half later, and stated that she had had no trouble with the toe since the operation. The scar was scarcely noticeable.

The notes on the condition of the other cases after operation are summarized as follows:

Case 1. Came to clinic regularly to be dressed, and walked about without marked inconvenience after the first day or two.

Case 2. Walked about considerably after the first two or three days.

Case 3. Walked two miles on seventh day. On thirteenth day walked three or four miles. No pain.

Case 4. Able to walk well from time of operation.

Case 5. At end of week walked well. Began work as elevator boy.

Case 6. Walked about on third day. No marked pain.

Case 7. Walked at the end of twenty-four hours, without much pain.

Case 8. Walked about with comfort after first two or three days.

Case 9. No pain after second day; then very little. Walked about well.

Case 10. Walked well about the house from first day on. Began work as saleslady seventh day.

Case 11. Walked on second day with little discomfort.

Case 12. About as much discomfort for four days following operation as for four days before.

Case 13. No discomfort except slight pain first night. Went to Coney Island on third day.

Case 14. On day following operation was taken to hospital for another ailment. (See history above.)

Case 15. For two months after operation there was slight tenderness about the toe, although the stitches were removed on the sixth day, and healing seemed then to be perfectly satisfactory.

Case 16. Was much more comfortable during the six days after the operation than those before.

Case 17. Came to clinic two days after operation, and again in four days. Walked with moderate discomfort.

Case 18. Very neurotic. On account of pain did not come to clinic to have toe dressed, but sent for a doctor. The pain and tenderness subsided after a few days.

Case 19. Slight pain first night. Slept well. Walked with moderate discomfort.

Case 20. No pain after operation. Three days after operation walked with comfort. Six weeks after operation patient said she walked better than she had for years.

Case 21. Fairly comfortable first two days. On fourth day pus was found and stitches removed.

Case 22. Walked two blocks on day following operation.

Case 23. Went to work after eleven days, standing at printing press. Fairly comfortable in the meantime.

Most of the patients suffered less during the week following the operation than during that which preceded it.

The average time at which the patients could be dismissed from attention was about two weeks, although many of them were told to come to the clinic longer than that.

There were, however, three cases in which considerable discomfort was caused by a new piece of nail starting from a bit of matrix which had been left behind by mistake.

This new nail grew out beside the other and irritated the side of the toe until it had reached the full length of the nail. In each case the ultimate cure was complete.

In ten of the cases there was healing by first intention, in nine there was slight granulation, and in four there was moderate suppuration. There was no sloughing of the flap.

In comparing this with other operations the question at once arises: What is the result if the flap does not unite by first intention, or with only a little granulation? Even then the healing is more rapid than by the "Cotting" operation, the one usually done here, since there is a smaller area of granulating tissue.

In one of the cases a Cotting operation had been done two months before on the other side of the same toe, and a considerable granulating area still remained. But in spite of the close proximity to this suppurating surface and a certain amount of suppuration which took place in the new wound, it healed before the Cotting and left an equally good result. The histories of these cases would then lead us to believe that we may expect rapid cures from this operation.

Nausea is said to be promptly relieved by a mixture of four drops of creosote in two ounces of lime-water. Dose: A teaspoonful every fifteen minutes.

TUBERCULOSIS.[1]

By M. P. OVERHOLSER, M.D.,

HARRISONVILLE, MO.

It is evident in bringing before you this subject for discussion that we can consider only a small part of the great field of thought and investigation it opens up before us. Recent researches along this line have added much to the literature of the subject, and have spread light and guidance in many directions. To review only a part of the work that has been done would be an endless task. Each day the enthusiastic worker in this field of labor tries to furnish us with some new plan of treatment or equip us with some new remedy with which to combat this scourge of civilized humanity.

So much has this subject been discussed of late that it is indeed well-worn, and to start out with a view of presenting to you something new and interesting would, no doubt, prove an unsuccessful task. In hope, however, of finding something practical, we have gone back to begin our search among the relics of the theories of the past, and have endeavored to traverse the ground from the old histologic teachings of Virchow, down to the all-abounding bacteriologic teachings of to day. The greatest event of this period was the discovery of the tubercle bacillus by Koch. This discovery revolutionized the theories and teachings concerning the nature of tuberculosis, and seemed to illuminate the very kernel of the subject. By this single stroke old and much-debated questions were apparently solved, and many of the mysteries surrounding this obscure disease were viewed in a new light. Clinical medicine hastily accepted the new doctrine, and frankly interested itself in the reconstruction of views which it imposed. So great was the change wrought that the tubercle bacillus seemed to be the all-important factor of the disease, and, as some one has said, "it became the one fixed fact in its pathology, and was soon universally regarded as the acknowledged centre about which all phenomena of the disease must revolve. Thus the study of the etiology of tuberculosis became simply the study of the life-history of the tubercle bacillus; its symptomatology, the effect it produced in the body; the definite diagnosis, the recognition of the bacillus in the discharges or tissues, and the therapy, the use of agents which would destroy it or prevent its growth in our structures. Whatever views, theories or hypotheses that would not fit in with these teachings were relegated as obsolete lumber to chapters on the history of the disease."

It is hardly necessary that I should review some of the facts, and many of the theories, that seemed to confirm the generally accepted opinion that the bacillus of Koch was the sole cause of the tubercular process. The foremost bacteriologists, pathologists, and clinicians of the world accepted this with a unanimity scarcely ever before or since witnessed in any scientific discovery. And thus it was that the great leaders of this new doctrine set to work to find some remedy or device some means with which to destroy in the body the micro-organism that was believed to be the sole cause of this dread disease that annually stalks through our land claiming its victims by tens upon tens of thousands each year.

The medical world waited with anxiety for the discovery of the specific, and perhaps the most dramatic event in the history of modern medicine was the announcement of Koch's experimental work with tuberculin in his earnest search for this much-hoped-for microbe destroyer. The reception of his labors was, for a time, enthusiastic and promised us much; but the failures that followed the general use of his remedy soon caused an adverse turn of public and professional sentiment, until, to-day, Koch's tuberculin is practically a thing of the past. Disappointing, however, as these results were, the work continued along the same line, and still we are in search of a specific medicament with which to deal a death-blow to these micro-organisms when they invade the human economy.

In the meantime the profession has again turned to the use of creosote. Discovered by Richenbach as early as 1830, it quickly secured a reputation in Germany, France, and England as a remedial agent in pulmonary disease. However, it gradually fell into disuse; but in 1877, through the admirable clinical paper of Bouchard and Gimbert on its beneficial effects in consumption, it was again taken up, and now seems to be gradually receiving increased favor from the profession. Some observers who have used this remedy have come to the conclusion that the good results which they have obtained from creosote are due to its specific action upon the process of disease, and have even gone so far as to try to make us believe that we have finally found in creosote a medicament which in itself is almost a specific for tuberculosis. Others tell us that creosote is without any influence upon the tubercular process, and no influence whatever upon the tubercle bacilli, and that the efficiency of the remedy depends upon its anti-fermentative power in the digestive tract. Creosote, they say, arrests or diminishes stomach fermentation, so frequently present in tubercular patients, and thus it favors nutrition and assimilation by increasing the appetite, promoting absorption, enhancing digestion, and in this manner the body-weight increases while the subjective symptoms—cough, expectoration, and the hectic phenomena—in the favorable cases disappear.

That creosote does have a beneficial effect upon some cases of tuberculosis is now being generally conceded, and cases of permanent cure are frequently reported, but the consensus of medical opinion is that its efficiency is not due to a direct action upon the tubercular process or tubercle bacilli.

In fact, we ask what medical remedy have we found that has proven to us in our observations and clinical experience that it has a specific effect upon the bacillus of Koch? We certainly do not administer our tonics, alteratives, and tissue-builders with a view of attacking directly these microbic invaders, and thus succeed in breaking up their colonization in the tissues of our patients! We certainly do not send our patients to the mountainous regions to breathe the pure air of higher altitudes, believing that the rarefied atmosphere of these regions will have a direct destructive effect upon the bacilli! And what better treatment have we, or what better advice can we give our patients! We ask again if all our treatment—climatic, hygienic, dietetic, gymnastic, medicinal, etc.—is of value in so far only as it adds constitutional vigor, increases the life-force of our patients and holds at a stable equilibrium the expenditure and supply of vital energy in the metabolic processes of the body?

This brings us to the chief point of our paper, and with due regard to the discovery of Koch of the bacilli, and the teachings of his followers, we have reasons to believe that there are other factors equally as important in the causation of this malady as the part played by the microbe.

Someone has said, "With a proper regard for the etiologic part played by micro-organisms in the drama of disease let us not mistake the cause for the effect—the organism is not the disease. Living, as we do, in the midst of myriads of disease-producing agencies, existence would be but a series of infection were it not for some kind of barrier placed between us and disease. Something more than seed is necessary for vegetable development. Not less important is soil. So, in the treatment as in the prophylaxis of tuberculosis, it is the constitution and not the germ that requires attention."

With reference to the report of the Second Congress for the Study of Tuberculosis, held in Paris from July 27, to August 2, 1891, it is said that if there is one thing above all others to be learned from the many discussions upon this well-worn but still obscure subject of tuberculosis, it is that the bacillus alone does not constitute the disease. The host is obviously not the least important element,

[1] Read before the Hodgen Medical Society, July 6, 1893, at Harrisonville, Mo.

and the only hopeful means of conquest must be on the lines of physiological resistance. The soil must be rendered sterile. A healthy condition of tissues and fluids best fulfils the indication in that it is antagonistic to bacterial growth and activity. One author says: "Writing in the light of many months' world-wide trial of Koch's remedy, I see in the present resources of medicine no means of directly or indirectly destroying the bacillus or of preventing its destructive action save by reinforcing the tissues. Nor do I conceive it within the range of probability that a specific in this disease will ever be discovered. Specific medication in tuberculosis while it may not be irrational is certainly misleading, for it is directed to simply an effect, or a secondary result of a fundamental cause which lies anterior to, or prior to, the invasion of the system by the bacilli." Solomon Solis-Cohen, Lecturer on Special Therapeutics in the Jefferson Medical College of Philadelphia, who has written an excellent article on tuberculosis, not long since, says, "that the bacillus of Koch, while it is perhaps the most important of several microbes that influence the progress of lesions in the various forms of this disease, does not of itself originate the disease in any form."

We must all acknowledge that there is in the constitution of the individual, anterior to bacillary infection, something that determines the fact of infection, and that largely determines also the course and character of the results of infection. Parasites thrive only under certain conditions. Remove the conditions which are favorable for their propagation and they disappear. "You take away their lives when you take away the means by which they live," has been well said.

Experience compels us to acknowledge that the healthy organism has great power of resistance to the bacillus, which can make an effective and permanent settlement in the lungs or other structures of the body only when certain favorable conditions are present.

Upon this point we desire to speculate. That which has been called "individual susceptibility," "predisposition," "lack of resisting power" to the bacillus, "a favorable soil," or "good culture medium" for the bacilli, is a determining element, a pathological something, a departure of some kind from the normal chemico-vital processes of the body, and is of itself a disease, primary to, and a prerequisite for, a successful invasion of the system by these parasites. Clinical experience teaches us this plainly. How often do we see in hereditary cases this underlying cause transmitted from parents to children, and whole families of comparatively young persons, with compact bodies, stout muscles, and natural color, quickly become victims of this disease?

There is no fact that seems so firmly established as the inheritability of this underlying cause of tuberculosis, and yet, after the discovery of Koch and his followers, so difficult was it to harmonize his theory with this clinical fact that, strange to say, the possibility of hereditary transmission of this fundamental factor of the disease was even denied by the adherents of the theory of the parasitic doctrine. But it was not long until the old view that was founded on clinical evidence was believed to be right. Various hypotheses were then soon started in explanation of this fact. Some observers told us that the child was born with tubercle bacilli in some of its tissues, and that the bacilli remained inactive for years. The long latency of the bacilli in childhood, however, was a special difficulty to be solved. It was then said that the fœtal and infantile tissues were more resistant to microbes than the tissues of the adult, and that the resistance of embryonal and infantile structures kept the bacilli in a, so to speak, "larval state" in the lymphatic glands, marrow of the bones, etc.

Such ingenious theories and others of a like nature were given us as an explanation for facts and phenomenon observed in the disease, but not well understood.

It was believed that all theories must harmonize with the prevailing idea that the bacillus was the primary, and, in fact, the only etiologic factor of tuberculosis.

The enthusiasts of a period of progress, of activity, of work in this department of medicine, have taught us much, but still there no doubt lie hidden in the realms of truth facts that are yet waiting for the eye of the discoverer, and that must be revealed before harmony can prevail between clinical observations and theoretical teachings.

Facts that have just been brought to light may be explained by new theories, but new theories can never change old facts. No matter if theoretical teachings must fall, and significant revolutions in practice follow, the accumulated results of clinical experience, the views founded upon observation and maintained from generation to generation, causes and effects long ago observed, and to-day recognized by all whose eyes see when removed from the microscope, must not be lightly set aside.

That there is a cause of tuberculosis, inherited and acquired, regardless and entirely independent of the bacillus and of a primary etiologic importance, is being recognized and admitted by students of the disease of to-day.

Periods of great activity and growth in any department of medicine are followed by intervals of rest.

We are prone to follow the enthusiasts and extremists in their earnest search for truth until we find that the results of their experimental work disappoint us in our expectations. Then stopping to sift and carefully examine that over which we have passed, we must settle upon facts and opinions as a basis on which to continue our work anew.

We admit the truth of Koch's discovery—a fact that cannot be denied. We acknowledge the presence of Koch's bacilli in most cases of tuberculosis. We believe that the bacilli are parasites that live and thrive only under certain conditions, and that these conditions are the result of some pathological state of the tissues, which, if successfully remedied, will permit the microbes to come and go harmlessly.

Within the cell, the ultimate morphological element of living structures, lies many mysterious processes and potentialities — processes physiological and pathological, energies latent and active, changes which are yet puzzling the physiologist, pathologist, chemist, and microscopist. Within the protoplasm, the living matter of the cells, resides a vital force, an energy which enables this living matter to transmute physical and chemical actions into vital processes, and to transform inanimate matter into the material basis of life.

We recognize that any force is simply a mode of universal energy, but the immediate origin of vital force of any living structure is its parent cell. It is true that the life of the cell must be afterward maintained by the conversion of other forms of energy into life energy, but the potential energy that is transmitted from parent to offspring is an important factor in the determination of the length of life of its progeny. We can see this plainly in both the vegetable and animal world. A plant may grow to maturity, bear fruit, and die. It may die not because the conditions which surrounded it were unfavorable for its growth, but simply because it was endowed with an original quantity of vital energy just adequate for a certain result and no more. The elephant lives longer than the horse, not because the conditions which surround one animal are more favorable or unfavorable to life than that of the other, but simply because within the living protoplasm of the one lies a potential power, inherited from its parent cell, which enables it to keep up the vital functions of life for the greatest period of time.

This vitality of the cell, which is originally a potential energy transmitted from parent to offspring, lies, we believe, at the foundation of the determining cause of tuberculosis.

The tubercular parent, with scarcely enough vital force to maintain his own existence, transmits a deficient potential vital energy to his progeny.

All the functions of life are simply manifestations of

force. When our Creator breathed into man the breath of life, He breathed into him potential powers, latent forces and energies that were to maintain his individual existence only for a period of time. He had provided a mortal frame in which the forces of the material world, through physiological and chemical actions on matter, could be transformed or converted into life energies. For life energy is simply a mode of universal force, and it is by the continual supply and discharge of this force in vital structures that the life of the structure is maintained, not perpetually, however, but only to the point of exhaustion of the potential or reserve energy of the living body.

In the destructive and reparative processes of tissue-change there is a liberation and a reaccumulation of force, and as this building up and breaking-down process is continually going on in the body, it gives us a circulating energy which is being constantly discharged and reaccumulated in these positive and negative phases of metabolism.

Besides this circulating energy there is a latent energy in the cells of vital structures, which represents a quantity of potential force by which the functions of life may be kept up for more or less prolonged periods of time without the supply of force from without. It is this reserve power that has safely carried many an individual over the crisis of disease by keeping up an amount of circulating energy sufficient for the maintenance of the functions of life when disassimilation of tissue, and consequent expenditure of force, exceeded that supplied from without by nutrition and assimilation.

That the immediate origin of this potential vitality is the parent cell cannot be questioned; and the more we study life in its various forms, the more evidence have we of the different potential capacities of the parent cell from which it came; and by a still further investigation into some of the problems of heredity we are forced to conclude that this potential vitality of any living structure is a quantitative inheritance from its parental ancestry. For if we find qualitative characteristics, such as likeness in form, features, disposition, etc., to be hereditary qualities, just so should we find potential energies to be hereditary quantities.

The germ-cell is potentially alive with qualitative and quantitative characteristics of its parent cell. The causes of prepotency by which the maternal and paternal characteristics prevail in parts, or in the entire structure of the offspring, is not known, but that these ancestral characteristics are transmitted from parents to descendants cannot be denied.

We say, then, in accordance with some of the late teachings on this question, and in the words of other authority than ours, that congenital tuberculosis depends upon a quantitatively deficient inheritance of original energy. Acquired tuberculosis depends upon any condition that reduces the quantity of potential energy below that inherited, or below the quantity required for the normal cellular activity of healthy structures.

A germ-cell thus congenitally deficient in vital energy may fail to reach its full development or growth. It may break down at the period of puberty, or at the period of reproduction, or under any condition in life that would cause an excess of expenditure of vital force beyond that supplied.

When we come to study the different pathological processes of the body, in none but tubercle do we find such a marked lack of cellular vitality. In inflammation cellular activity is increased. Here there is an abnormal excess of tissue-building—a process in which the inherent vitality of the part is plainly seen by an increased afflux of blood and a rapid multiplication of cellular structures. It is a process also that tends to termination either by resolution or suppuration, and if by suppuration the vitality of the surrounding parts quickly replaces the tissue destroyed or repairs it by a durable cicatrix.

In the growth of neoplasms, where there is a perversion of the normal tissue-building power of the part, the new structure acquires a certain degree of organization and tends to persistence in its growth. Tubercle, on the other hand, is a morbid cell aggregation so devoid of vitality as to be unable to progress into the parent-cell type, into a durable neoplastic growth, or even into a cicatrix cell. It is simply a progeny of cells so deficient in potential energy as to be unable to complete their development into any kind of durable tissue.

In reticular miliary tuberculosis Gibbs says the tubercle consists of a degraded type of cellular structure that increases from the centre of the tubercle, compressing the reticular tissue toward the periphery, and which is prone to undergo necrosis.

There is no tendency to reaction in this pathological process. It is not a death of the part in healthy structures by the destructive action of little colonies of bacilli, but simply a retrogressive course of tissue-building—a formation of tissue elements so degraded in type, so low in vital force as not to be able to maintain their own existence.

If they were localized areas of destroyed tissue, the result of bacillary infection, would not conservative nature at once summon her latent forces, and with an increased cellular activity of the contiguous parts of the infected area surround the destructive agents with an inflammatory barrier and seek to prevent an extension of the process by preventing further invasion of these micro-organisms into her healthy structures? And if successful in this, after she had cut off the supply of her intruders until they perished, would she not then follow her usual course, under similar conditions, by replacing the destroyed tissue or building in its stead a durable cicatrix? But not so! There is not even vital force enough in the contiguous structures to bring about a healthy reaction as a conservative step in the limitation of the process. Still further in accordance with this view Gibbs says that in reticular miliary tuberculosis careful examination of numerous sections, stained by the most approved processes, often fails to reveal any bacilli, even though hundreds of sections are examined.

In chronic localized tuberculosis the process is different. Here there is a tendency of reaction of the organism. In the lung, for instance, where there is consolidation, we find it surrounded by new fibrous tissue. In the disintegration of this consolidated tissue in pulmonary tuberculosis we find a condition very favorable for the propagation of bacilli, and in many of these cases the sputa is found to be swarming with bacteria. It is this form of tuberculosis that seems to be simply a warfare between the bacillus, on the one hand, and the vital strength of the tissues on the other, the fate of the patient depending most largely upon the vital energy resident in the part attacked.

Henry P. Loomis, of New York, says: "After a careful study of the processes which result in the arrest or cure of this form of tuberculosis, that of seven hundred and sixty-three persons dying of non-tubercular disease, seventy-one, or over nine per cent., presented in their lungs changes characteristic of healed tuberculosis, and other observers tell us that their clinical experience and post-mortem examinations prove to their minds that the reaction against these infective microbes is so marked in some constitutions as to even bring about spontaneous cures of tubercular disease without the aid of therapeutical measures."

By a careful study of nature's own efforts in coping with this affection we find that her success lies along the line of physiological resistance of the tissues to the microbe. If she fails, her failure should not be attributed to the destructive effect and infective nature of the bacilli, but to a lack of sufficient vital force to properly maintain the integrity of her own structures, in consequence of which these parasitic agents which float in the air we breathe, and lurk in the food we eat and the liquids we drink, find a suitable lodgement for their growth, a favorable soil where they can live and thrive upon a pabulum furnished them in poorly organized tissue. A colony

once established (aside from surgical means) can be eradicated only by nature's own process. Fibrosis is her conservative and protective step, a process resulting from augmentation of cellular activity, simply an increase of a normal constructive phase of metabolism, accomplished only through a potential energy of the living cells of the part which acts as a bulwark to prevent the irritation and extension of this tubercular process, or the destructive effect of the bacilli.

Let it be understood, then, that we believe the great factor in the causation of congenital and acquired tuberculosis is a deficient vitalization of the cellular structures of the part affected.

The high potential capacity of living protoplasm we believe to be the potent factor in the protective and curative efforts of nature, therefore it is this fort that we must strengthen in the management of our cases if we expect our treatment to be productive of good results. We will not have time, neither do we intend, to specialize in treatment.

In a general way, we would advocate the renewal of vital energy by any and all methods through which it can best be accomplished: More general vitalizing treatment directed to our patients, and less specific medication directed to the microbe; an abundance of food, air, light, and sunshine; alimentary and respiratory diet, rich and free; tissue builders laden with nitrogenous and hydrocarbonaceous compounds. Nitrogenous elements, the great liberators of force, and hydrocarbons, the great storehouses of energy, must be supplied in abundance. Oxygen, the great purifier and revitalizer of diseased structures, must hold a prominent place in therapeusis. All measures to keep up vitality and revitalize diseased structures must be foremost in the mind of the therapeutist, remembering that measures which favor the nutrition of man oppose the nutrition of harmful bacteria. Fight the enemy by strengthening your own fortress. Do not spend valuable means and time in useless efforts in attempting to destroy or eradicate a universal foe, which lies waiting to attack the weak on every hand, but guard well your frontiers, build up your barriers of defence; for fortification against a further invasion of such an attack is safer and wiser than to seek protection by useless attempts to destroy the enemy.

We believe, if a successful treatment of tuberculosis is ever attained, that the microbe will be practically forgotten, and that the therapeutical measures will be directed to the condition of the system upon which the bacilli thrive.

MALIGNANT GROWTHS OF THE SKIN, PARTICULARLY OF THE FACE[1]

Their Early Recognition and Treatment.

By WM. THOMAS CORLETT, M.D., L.R.C.P. Lond.,
Professor of Dermatology in Western Reserve University, Cleveland, O.

It is not the purpose of this paper to enumerate all the malignant diseases of the skin, nor to detail all of those that are known to attack the integument of the face, but rather to call attention to certain affections having a special predilection for this region, which, according to the writer's experience, especially merit attention at this time. For it is to medical men engaged in general practice that those afflicted with the conditions to be considered first apply for aid. For this purpose, and to present the subject briefly, but two cardinal pathological conditions will be considered—tuberculosis and epithelioma—they being the malignant growths most commonly encountered and upon whose early recognition and prompt treatment so frequently depends the patient's life.

By tuberculosis of the skin we mean an inflammatory condition occasioned by the presence of the bacillus tuberculosis, which leads to gross destructive changes in the part attacked, from which it has been named lupus. Two varieties of this disease are met with—lupus vulgaris and lupus erythematosus. The first is encountered early in life and most frequently appears during the second decade. Lupus erythematosus seldom appears before thirty, and from the greater resistance the skin acquires against this bacillus at this time, it appears in a milder form, is not accompanied by the disfiguring loss of structure which characterizes lupus vulgaris, and less frequently leads to a fatal termination.

Confined to the skin lupus is fatal to the integrity of the parts affected, but not to the life of the patient. It is only when it extends to the internal vital organs that it becomes a fatal disease. As it most frequently attacks the face, particularly the nose and ears, its close proximity to the mucous surfaces facilitates its fatal extension to the meninges of the brain and to the pulmonary tract.

Jonathan Hutchinson was wont to maintain that the lupus process seldom extends into the air passages, although it was frequently encountered on the gums, tongue, and sometimes in the œsophagus. He had seen it in the rectum in one case. Unfortunately this immunity of the air passages does not obtain in Northern Ohio, as shown in the following case, which is selected from others of the same kind:

Case I.—Annie N——,[1] aged thirteen; delicate; mother died of phthisis two years previously. When the patient came under my care, November 24, 1890, one year after the onset of the disease, there was present a dark-red spot, about the size of a silver three-cent piece, on the right cheek. Irregularly scattered about it were millet-seed-sized papules or tubercles. They were not elevated above the surrounding skin and the central lesion was even slightly depressed. This latter was covered with loosely adherent scales and a few small crusts, upon removal of which an irregular, easily bleeding surface was exposed. The right lower half of the nose was also involved, as was the nostril of the same side, which from the inflammation and cicatrization resulting therefrom had contracted the opening to about half its normal size. In dilating the orifice sufficient for an examination it bled freely.

The patient was given the potassium iodide to full toleration and the compound tincture of gentian. Locally an ointment containing salicylic acid, grs. xxv.; oleate of mercury (ten per cent.), ʒ j.; and vaseline, ℥ j.

On December 6th the eruption showed a marked improvement, but the potassium iodide was ill borne and recourse was had to a pill containing iron, arsenic, and strychnine. This line of treatment was followed until October 1, 1891, at which time the eruption remained *in statu quo*. Repeated scarifications were then begun, as recommended by Vidal and others. After scarification, the surface was touched with creosote, and capsules of creosote were given internally.

December 25th.—The eruption was better than at any time since the beginning of treatment. There was, however, a grayish-white patch surrounded by a bright-red areola on the mucous membrane of the lower lip.

December 26th.—A lesion similar to the one last noted had now appeared on the roof of the mouth, about an inch in front of the uvula.

Soon after this it was noticed that the patient was losing flesh rapidly; she had a cough, and upon examination moist râles were detected in both apices. The patient grew worse rapidly and died of phthisis during the summer of 1892.

Although the lungs afford a favorite seat for the grave sequelæ of lupus, yet other structures may become involved, as in the following case:

Case II.—Maggie R——, aged twenty-seven, seamstress, family history free from tuberculosis in its various forms, developed a patch of lupus on right cheek at the age of seven years. It was about the size of a twenty-five cent piece and remained in a quiescent state until the age of puberty, when it assumed a more active condition. I saw the case for the first time February 16, 1884. At

[1] Read before the Ohio State Medical Society, at Put-in-Bay, June 28, 1893.

[1] Clinical lectures at the Hospital for Skin Diseases, Blackfriars, London.

this time the face was badly disfigured. Scarification, caustics (the nitrate of silver and the acid nitrate of mercury), and the internal administration of iodine and cod-liver oil were employed, but the disease extended. Finally the external auditory canal was attacked and completely occluded with exudative material. In this position local measures could be but ineffectually applied. About four months after, the patient complained of deep-seated pains in the ear, followed by delirium and death in September, 1886.

The autopsy revealed an accumulation of pus in the internal ear, and tubercle nodules in the meninges of the brain on the corresponding side.

Even more frequent as well as more fatal than tuberculosis is the rebellion of cells known as epithelioma. By this term we designate an infiltrating growth in the skin composed of cells of the epithelial type. Epithelioma has likewise a subdivision in rodent ulcer, which differs but little in histological structure from cancer, yet from its course and clinical aspects it is entitled to a certain distinction, if not to be regarded as a disease *sui generis*. (According to Thin the cells of rodent ulcer have a uniform nucleolus, a non-granular protoplasm, and is characterized by the absence of epithelial nests.) Whether with Malassez, Albarran, Cornil, Dubreuilh, and Wickham, we accept the theory of the psorospermoses, of this we are certain, that epithelioma develops in those parts of the skin which from their exposed position are subjected to irritation, or from repeated injury; as a consequence they are less liable to resist the invasion of an external foe or to regain their healthy tone after slight though repeated departures from the normal.

Believing that the various lesions and anomalies in which epitheliomata so frequently develop are at the onset distinctly local affections, it becomes necessary to speak of them as a premonitory condition. With epithelioma when developed, text-books are sufficiently explicit to make it easy of recognition, and need not further concern us here; but it is when the death-dealing process lurks behind the mask of the simple anomalies of the skin, or in the simple and at first benign pathological disturbances of its structure, that we wish especially to emphasize at this time.

Of the congenital anomalies of the skin which after the fourth decade of life become cancerous, the papillomata stand at the head. In these the histories present a marked similarity in that at a certain time the wart was injured, or that at times when irritated it became red and slightly painful. This condition may have continued for months or years, when finally, from some lowering of the general systemic tone the well-recognized characters of a malignant growth appeared. In the acquired papillomata the transition from the benign to the malignant is usually more direct. Neither does the presence of pigment exert any influence in determining this unhappy termination. For example, the lip has been exposed to the irritation of a pipe or a cigar; as age advances it shows the effects of this long-continued local stimulus in the form of an hypertrophy—in this it but follows the natural law. In some there appears at the focus of irritation a variously sized and shaped villous growth—a papilloma—on others this gives rise to an abrasion. Months and years go on, the part is subjected to the round of plasters and ointments, all more or less irritating, until finally, under this systematic cultivation, its malignant nature becomes strikingly apparent.

In the same way certain diseases of the skin predispose to epithelioma. Especially is this true of the derangements of the sebaceous glands. For this reason acne is always a source of menace to old people. What is even more common in the aged than acne is the form of seborrhœa of the face, which has been aptly called by the French *séborrhée crouteuse*. This appears in the form of variously sized plaques, slightly raised above the surface, of a yellowish-brown or muddy color, firmly adherent, and when forcibly detached presenting a base not unlike that in erythematous lupus. These sebaceous plaques usually break down late in life, and not infrequently give rise to epithelial cancers.

Several cases are on record in which epithelioma has been engrafted on lupus of the face. I have a photograph of an epithelioma occurring in the cicatrix of lupus, the two diseases existing side by side. The patient was an old woman, who had been afflicted with lupus vulgaris since the age of twenty. At the age of fifty-three the malignant sequelæ herein shown appeared.

Treatment.—It is of the first importance that treatment be begun early in the history of the disease. For this its early recognition is necessary. Again, the ultimate success will depend upon the thoroughness with which the procedures adopted are carried out. The diseased process being confined at first to the structure of the skin, local measures are the ones upon which we must rely. It must also be borne in mind that in both lupus and cancer a vitiated constitution will enable the disease to pursue a rapid course. For this reason the general management of the case should never be lost sight of. Proper hygienic surroundings, good food and the ability to appropriate it, should if possible be maintained. For this the vegetable bitters, iron, and in some cases cod-liver oil, will be indicated.

In the local treatment of lupus thorough destruction of the *materies morbi*, and care that the adjacent healthy structure be not exposed to contagion, are the first objects to be attained. Further than this the method may be largely a matter of individual preference; those most in vogue are, first: Destruction *in situ* by caustics, such as the stick of nitrate of silver, pyrogallic acid, the galvano-cautery, etc. Second. Enucleation with Volkmann's spoon and cauterizing the walls of the cavity by either of the above; or, what is, I think, better, carbolic, sulphuric, or salicylic acid. In this latter procedure there is danger of reinoculating the patient as well as of infecting the operator, for the tubercles are very vascular and blood is with difficulty prevented from entering the nostrils and mouth of the patient, while the apple-jelly contents of the tubercles readily spatters on to the operator's face and may be inhaled by himself and his assistants. To obviate this I adopted the *thermo-cautère*, of Paquelin, about six months ago. The result has been highly satisfactory, for immunity is not only afforded to others, but by its use the destruction can be more thoroughly performed, and the walls of the cavity infiltrated with tubercle bacilli, although they offer a firm resistance to the scoop, hold out no barrier to the actual cautery. Even in the milder form, lupus erythematosus, I believe the thermo-cautery offers the quickest and most efficient means of relief. In regard to the simple growths that lead to epitheliomata, their early destruction is the safest course, although the laity are thoroughly impressed with the *noli me tangere* sentiment and frequently object to their removal until the most favorable time is passed.

Papillomata of congenital origin, when on the face or where exposed to the friction of the clothing, should be removed early in life. For this purpose electricity offers the best means at our command. The process is known as electrolysis, and consists of the continuous current passing from needles which are thrust into the base of the growth. The strength should vary according to the size of the tumor, usually a battery of eighteen cells, or from ten to twenty milliampères of current, will be sufficient. This when carefully performed leaves no scar, and is devoid of the formidable procedure that necessarily surrounds the knife. In the papillary growths that appear later in life the same treatment may be adopted. For the small indolent ulcers that appear on the lips, as well as on other parts of the face, the pyrogallic acid (ten per cent.), salicylic acid in collodion (ten per cent.), or the Vienna paste when applied early, will prove efficient in many cases. Seborrhœic plaques may be removed by escharotics, but electrolysis is to be greatly preferred.

Finally, when epithelioma is actually present there are two methods which hold out the surest means of relief—electrolysis and the knife. My experience with the first

leads me to believe that thorough destruction along the channels of absorption can best be accomplished by its use, and that recurrence is less common than by any other method at our command.

SIMULATION OF DISEASED STATES FOR THE PURPOSE OF GAIN.[1]

By A. L. HALL, M.D.,

FAIR HAVEN, N. Y.

THE simulation of diseased states for the purpose of gain has become so prevalent among us that a few remarks thereon, suggested by a considerable experience with such conditions, are not only appropriate, I believe, to this occasion, but of timely interest as well.

As a form of deception, disease simulation has been practised from the earliest times, but its development to the point of a fine art has been reserved to the progressive ingenuity and refined influences attendant upon the high degree of civilization as lived by us to-day.

Of us, as a people, it can aptly be said, that as the result of our surroundings, we are rapidly becoming a race of "neurasthenics," and that, by reason of this tendency, we are predisposed to simulation. It is a well-known fact that many of us are disease simulators from birth. In proof of this assertion I instance the infant who compels obedience to its desires by simulating laryngismus stridulus, or of the disagreeably tasked child who, as a means of escape, opportunely affects a headache; and if further proof were wanting, I would only ask that you recall to mind the many cases of youthful disease imitation occurring within the observation of each of you.

It is not, however, of such comparatively innocent simulation I would speak, but rather of that baneful form of imposture which has for its object the obtainment of unmerited benefits or the securing of unjust compensation for doubtful injuries. The many weekly indemnity societies, the multitude of private concerns, and the countless corporations which fill our land are now, as never before, the subjects of innumerable frauds perpetrated by the ever increasing number of disease simulators. The detection of simulation, therefore, is a matter of great and increasing importance, and a study of this subject will doubtless impress you with the belief that the cunning and ingenuity of mankind greatly exceed that nobler virtue, honesty.

The consideration, then, of some of the forms of disease deception and their detection will constitute the basis of what I shall attempt to say within the brief time allotted to me upon this occasion.

Disease simulators usually affect the functional forms of disease, especially the types of nervous disorder known as the neuroses. In these simulated states the true objective signs of disease are wanting, but in many instances the simulation is so well maintained that false signs are sometimes—even by the most expert physicians—readily mistaken for real evidences of disease. Of the subjective symptoms there is ever a countless array. Pain, insomnia, mental depression, loss of appetite and bodily weakness are simulated conditions that are never wanting in the feigned states of disease. The most successful simulators are those possessing the nervous temperament, and if not in an actual state of neurasthenia at the time the deception was first instituted, they, through want of exercise and insufficient food, quickly acquire this condition, to which in nearly all cases there is sooner or later superadded the emotional or hysterical state. Thus it is that, in most of the cases of disease imposture, we are inevitably, as it were, brought to face the varied conditions of neurasthenia and its allied state, hysteria. And it matters not that if under such circumstances the neurasthenic state becomes, unconsciously on the part of the simulator, a reality; it is on that account none the less an imposture, and as such is deserving of the same measure of reproach as though it were wholly feigned, instead of being the direct product of feigning.

In a considerable number of instances simulation is deferred. At first the person suffers from a slight illness or a trivial injury, but instead of recovering from it within the usual period, he passes slowly and insensibly, but none the less for that with wilful and designing intent, into a state of apparent or real neurasthenia, attended generally with hysterical manifestation. Again, where the resulting ailment has been severe and the confinement more prolonged, simulation in the form of symptom exaggeration may occur. Symptom exaggeration may be present at any stage of the disease, but where it is maintained for the object of gain, it is most marked at the time that improvement would naturally follow.

In the absence of organic lesions or of some pronounced form of disease, the condition known as the hysterical or emotional state, in nearly all cases within my observation, has been nothing less than downright simulation. Regarding the truth of this remark there is little to contradict, while upon the contrary your individual experiences with the varied forms of hysterical manifestation will, I believe, fully sustain this statement.

Again, in many instances, the hysterical condition is no more an expression of a diseased state than are those states of our feelings which are called joy and anger. Easily excited, the hysterical manifestation becomes with many persons an effective and demonstrative form for the expression of some particular state of feeling—an agreeable substitute, it may be, for the concealment of anger. Furthermore, hysteria is so easily cultivated that it may quickly acquire in neurotic subjects those symptoms which constitute its gravest forms of manifestation. In support of this assertion I cite the universal agreement of all writers upon nervous diseases as to its occasionally epidemic appearance and apparently contagious character at such times.

The teaching that education and refinement conduce to the development of hysteria holds undisturbed sway in our minds, and at the same time we are as firmly led to believe that these causes are strong factors in the prevention and dissipation of disease. While such opinions are not so directly contrary as to appear paradoxical, still they provoke a strong feeling of scepticism, which medical minds have long felt, as to whether hysteria is a diseased state or not.

Hysteria has long been looked upon as a disease resembling or feigning all other diseases. This quality is its most notable and constant characteristic, and quite essential, I maintain, to its existence. And as partially stated before, I hold, in the absence of the true objective signs of disease, that with very rare exceptions, where gain is sought, the hysterical and neurasthenic states are simply a result of disease simulation provoked by the powerful and controlling influences of suggestion. Speaking of these conditions, when following the milder forms of injury, a writer states in substance: "Given the hypnotic or hysterical state of mind, sow the seeds of suggestion, and you can grow any kind of litigation-symptoms you desire." In my opinion, he could have said with equal or even greater force: Given the object of gain, rather than the state of injury, and in neurotic soil you can cause to grow and to thrive indefinitely the symptoms which constitute the condition known as hysterical neurasthenia. It matters not by what name you call this state, whether it be the same that I give to it—hysterical neurasthenia, or whether it be termed spinal anæmia, spinal irritation, spinal concussion, railway spine, railway brain, traumatic hysteria, or traumatic neurosis—the condition is ever unvarying, except as to time.

If the simulator succeeds, from the effects of confinement, want of exercise, and insufficient food, in reaching a real state of hysterical neurasthenia, you will be unable, it may be, to detect the simulation. If there be some

[1] Read at the twenty-sixth annual meeting of the Medical Association of Central New York, held at Rochester, N. Y., on June 16, 1893.

strong and influencing object of gain in view, and there be an absence of organic disease, you will be put on your guard against deception, but you may in some instances be better able to understand the nature of the case you have been dealing with when your patient has obtained the object sought, and then quickly, and perhaps without the aid of remedies, he rapidly recovers from a state that apparently was immovable under your best directed efforts of treatment.

Again, there may be symptom exaggeration. Of this condition pain has ever been a very noticeable form. The pain will usually, if not always, find its principal location in the spinal column. Its site may vary, but it will, usually, persist in spite of treatment. It is that kind of pain which is termed by many writers hysterical pain, but a more correct designation would be given to it were it called pain simulation. Suggestion excites it, whereas the withdrawal of the attention completely arrests it. In other words, it is that kind of pain which is brought into action and dispelled at the will of the subject. It is therefore a simulation.

Beyond the point of simple increased sensitiveness the special senses are not, as a rule, involved. Vision is most prominently affected, but the impairment seldom exceeds the condition known as simple asthenopia. Motor weakness is always evident, and it may proceed until it attains a degree approaching a true paresis or paralysis. Its feigned character is plainly seen from the ability of the subject to execute any desired movement with the affected parts. To a certain extent this muscular weakness becomes a reality similar in degree to the bodily state observed in the milder forms of simple neurasthenia, consequently their differentiation is impossible from an ordinary point of view. This bodily state should not, however, mislead you into the belief that it cannot be dependent upon simulation. When such condition has long existed and is present without evidences of organic disease you will do well to ascertain if the subject is not actuated by a desire for gain. Many times such a discovery will cause you to attach a different significance to the symptoms and will assist you in differentiating disease imposture from a truly diseased state.

Disturbance of the cutaneous sensation manifests itself in various ways, but chiefly in the form of anæsthesia or hyperæsthesia. These alterations of sensations are not real, but are imagined or feigned, and are subject to the will. The frequent and cautious use of the æsthesiometer, conjoined with the other tests for altered sensation, will convince you that such is the case; and furthermore, their employment will teach you that these apparent alterations of sensation undergo notable and conflicting changes as regards their form, situation, extent, duration, and intensity, and that such alterations are easily effected by the subject in response to the suggestions of the examiner.

The bodily functions, for the most part, are sluggishly or indifferently performed, but no more so than want of exercise and restricted diet would easily induce.

Insomnia and distressing dreams are usually complained of; but such subjects, when carefully watched, will be found to sleep well in spite of their protestations to the contrary.

Occurring under the conditions I have already indicated, hysterical neurasthenia should always be the object of our gravest suspicions, for arising from whatever alleged cause, it will be found, under these circumstances, to be largely, if not wholly, dependent upon simulation.

Many recent writers maintain that hysterical neurasthenia seldom or never follows the ordinary accidents of life, but that it frequently declares itself after accidents resulting from railway collision. Erichssen, who has had a large and varied hospital practice for upward of thirty years, states that he has never observed a single genuine case in which the emotional or hysterical state resulted from the ordinary accidents of life, but he states that he has frequently seen it follow cases of railway injury. Thus, except in cases of great concussive violence, he assigns hysterical neurasthenia arising from the milder forms of trauma to the domain of disease simulation. Either must this opinion of this great authority, who has done more to advance the cause of the plaintiff's case than have all other writers, be viewed in a different light than he would have us to do, or else we must accept his views upon this point, and thus agree with him that the state of hysterical neurasthenia arising from the ordinary accidents of life is only the result of a well-maintained simulation. While not coinciding fully with this opinion I believe that where gain is coupled with a mild form of injury the neurasthenia and hysteria which follows are, in nearly all cases, the result of conscious or unconscious simulation.

That the neurasthenic state, when following the milder grades of injury, is regarded as a doubtful state of disease, a partial simulation, as it were, the following quotation from Dana's article on spinal concussion fully attests. He says: "Traumatic neurasthenia is in a measure a real disease, though it is very hard to say how much is real and how much the patient puts on." "It may be, and is often simulated, and it requires the greatest care to detect skilled impostors." He concludes, by saying: "We need more objective tests for the purpose of determining the existence of these subjective neuroses."

In conclusion, I will briefly recapitulate, as follows:

In the absence of other disease manifestation the state of hysterical neurasthenia is ever the same condition, whether rising from well-sustained simulation or from other causes; consequently physical signs and tests are of no particular value, in determining from what cause the condition resulted.

Again, where the subject has some substantial object of gain in view and special disease lesions are absent, hysterical neurasthenia, when long continued, should be regarded with suspicion, and when claimed to have originated from slight injuries or other causes it should, with rare exception, be looked upon as a state resulting from simulation.

Finally, a desire for some form of gain, pecuniary or otherwise, is a strong and important factor oftentimes in the production of hysterical neurasthenia, and a knowledge of its existence is oftener a better means for the detection of simulation and fraud than are the physical signs and tests which are now at our command.

A somewhat spirited discussion, participated in by Drs. Crego, of Buffalo; Angell, of Rochester; Elsner, of Syracuse, and others, followed the reading of the foregoing paper. The opinions expressed by these gentlemen were apparently provoked in part by a misunderstanding of the actual views stated therein, as well as by an evident desire to sustain the commonly accepted doctrines respecting the nature and origin of neurasthenia and hysteria, which, in some degree, are controverted by the views I have advanced.

That the gentlemen who listened to the paper and its discussion may the better understand my real views of the subject treated, and also more easily perceive the error of the criticisms which were elicited upon this occasion, I have presented the original paper, not eliminating therefrom the ambiguity and partial contradictions which under other circumstances I would gladly have done. If the paper shall contribute anything toward the detection of simulation, or in anywise promote our knowledge concerning the apparently diseased states which may result therefrom, especially as regards the production of hysterical neurasthenia, I shall feel more than compensated for my labor, and will willingly bear the criticism which my views have invited, or may hereafter invite.

The Second Japanese Medical Congress was held in Taukiji on April 4th to 10th. Over twelve hundred members were present. It was decided to organize a Japanese Medical Association, with head-quarters in Tokio, and with a branch in each province of the empire. The name of the society is Dai-nippon-i-kwai.

Clinical Department

THE COLD BATH IN COUNTRY PRACTICE.

By JULIUS E. GRISWOLD, M.D.,

PORTLAND, CONN.

I AM an advocate of the water-treatment, as it is called. I believe, in fevers of any sort, and, so far as I can, am endeavoring to uphold it. Every little while I see a good article on this question, from some man who is in practice in the city somewhere, advocating the use of water as the great thing needed in the treatment of fevers to keep down the temperature; but many of them cast a cloud over their articles by saying that the treatment "cannot be carried out to good effect in the country." This, of course, leads many a good man practising in the country to think: "Well, there is no use for me to undertake it." Now, this reasoning is all wrong. Of course, we cannot always command all the things needful and perhaps seemingly necessary to carry out well the systematic treatment as it is laid down by the authorities, but that is no drawback and is no reason why those of us who are so fortunate as to do country practice should stand by and see the patient struggle with a high temperature day after day and week after week without using the great remedy given us by nature. I never allow myself to hesitate one moment when taking hold of such a case, but begin immediately with sponging with cold water, and the higher the temperature the colder the patient likes the water after the first few times applying. At least I find it so, and I think such will be the case with anyone who tries it. Of course, the temperature will not always yield to sponging, and then I resort to the bath, in bath-tub, foot-tub, or ordinary wash-tub, according to the size of the patient and the things I may have to do with. I never have the patients wiped, but wrap them in sheets, and in the case of small children a blanket outside that. Now, in order to carry this out well, one must lay down the law to those who have the care of the case that it must be done often enough to "keep down the fever," and no man should go in for such treatment unless he believes in it and wants to carry it through. When one takes a child, nine months old, with a high fever, from its mother's arms and deliberately puts it into a tub of cold or cool water, the child crying at the time, he must believe in what he is doing or he can't well do it. This I have done, and had the patient tremble and shiver for a few seconds, but under the grateful effect of the cool moisture to the hot skin in a short time the scene changes. The eye grows clearer; the temperature goes down; the skin feels cooler; the wandering moan of the patient, due to the fever, ceases; and after being put in a sheet one has before him a patient more quiet and comfortable than could have been got from any other treatment, I believe. This continues until the fever rises again, when the thing should be repeated, no matter whether it is one hour or ten. Sometimes I have seen sponging with the water do this when the temperature does not go above 104° F. I have taken cases where there had been no sleep for days—nothing but toss and turn, over and over, and where all sorts of anodynes and antipyretics had been given, and in ten minutes after being put into cold water the patient has been asleep. Now, after seeing this it is not possible for any man to convince me that there is any better way. Of course, it is not likely that what I say or write will make any great stir, but I hope that some man who lives where he has to depend on his own judgment will be influenced to realize that he has a mighty power for good in cold water, and will pull off his coat and go at it, believing that he is on the right track. To carry out the idea well one must deal with people who will allow him to do as he chooses, and my way is to refuse to have further to do with the case if I am not allowed to conduct it according as seems best to me. I have found that it is well to leave a thermometer with the mother or wife, if you have no nurse, and instruct them as to its use, telling them that when the mercury rises to a certain point the case is to be sponged or put into a bath. I also find that as soon as those who have the care of the patient see the good effect from the use of the water they learn to depend on it and like it. Also, the patient often will say, if old enough, "Sponge me all over now, and I can go to sleep." Many times in the past fourteen years I have had that reported to me the next morning. Those of us who live in the country should not feel that we can't do this, for it can be done, has been done, and will be done, I believe. Knowlton, of Ann Arbor, Mich., makes a canvas bath-tub that can be set on two ordinary chairs, the bottom, when full of water, resting on the floor. This can be folded, I think, when not in use. Such a tub can be used in any room, and it is not necessary to change all the water every time, only taking out and putting in enough to change the temperature. Of course, everyone must be guided by his own actions as to treatment otherwise, besides the use of water; but I do not believe that medicine has any beneficial effect on the temperature.

AN OPEN SAFETY-PIN SWALLOWED.

By W. D. GROTON, M.D.,

RIVERA, CAL.

DR. SULLIVAN'S report, in the MEDICAL RECORD of August 5th, of "An Open Safety-pin Swallowed," recalls a similar case in my own experience, while practising in Susanville, this State.

On September 16, 1884, I was consulted by a young rancher, whose baby, fourteen months old, had just swallowed an open safety-pin. His wife stated that she had used the pin, a small one, to fasten its bib. A sound of strangling and gagging attracted her attention, and she reached the child just in time to see the pin disappear, open, down its throat. Beyond a little gagging the act seemed attended by no particular difficulty, and when I reached the child she seemed happy and cheerful. I was incredulous as to the pin being open, but the mother was positive, and evidently sincere, stating that the pin didn't "catch good," and she had seen it open in the baby's bib after she had fastened it, but didn't think the child could get it out. I explained to them that the child's effort to swallow the pin had probably closed it, and it would doubtless pass away all right in due time. But even should it be open, a laxative (already prescribed by the neighbors) would do more harm than good, and advised them to trust to nature and await events.

Four days later the father brought me the pin, a small nickel-plated one, still open. He assured me that he saw it himself in the child's diaper, open, just as I saw it. The baby had cried lustily while passing it, but otherwise had not appeared in the least discommoded.

BICHROMATE OF POTASSIUM AS AN EXPECTORANT.

By JOHN E. WEAVER, M.D.,

ROCHESTER, N. Y.

HAVING just been reading the item with this title in the MEDICAL RECORD of August 12th, I wish to add my testimony to the great value of the drug as a remedy in affections of the upper air passages. It is especially useful in both laryngitis and bronchitis, if the secretion is tough and stringy, and hard to raise. On using this remedy there is an almost immediate change, the expectoration is loose and easy, and rapidly disappears, and with it the local trouble which is its cause. I value the remedy still higher in tonsillitis, where the onset is rapid, the tonsils rough, raw, and angry looking, with a muco-purulent secretion exuding from the follicles, and gradually spreading over the tonsils; also in all cases of non diphtheritic pseudo-membranous tonsillitis this remedy is so sure in its effects as to merit the title specific. In treating laryn-

gitis and bronchitis with this remedy one must be careful not to use it too strong—not more than one grain well triturated to three or four ounces of water, a teaspoonful every one-half to two hours, as suggested by Dr. Hunt. But in tonsillitis the finely powdered bichromate should be added to water until the latter is of a dark lemon or light orange shade, and of this a teaspoonful should be given every hour. In these cases the only limit to the administration of the drug is nausea. If this symptom appears, lessen the dose, and, if necessary, the frequency, and no other remedy need be thought of. Tell your patient he will begin to improve by the third dose, and he will. But do not try weak solutions, or powders, or tablet triturates for the tonsillitis, or you may get disappointed. The solution is the form, and the color indicates the strength.

BIRTH IN THE COFFIN.

By H. ROSANSKY, M.D.,

NEW YORK.

In the MEDICAL RECORD of July 29, 1893, is an account of a birth in the coffin.

Ten years ago I was appointed by the Russian Government as country physician to the city of W——. While there I saw a case where a young woman died in full term of pregnancy. On the second day after death the country people of that place took the cadaver and put it in a hot Russian vapor bath at 30° Reaumer for two days, and had an old woman to watch it. On the evening of the second day the abdomen was fully distended and uterine contractions occurred, as if in a live subject, and the child was expelled. The woman also delivered the placenta. In some parts of Russia there is a law that women who have died pregnant shall not be buried until the delivery of the child has taken place.

It is also a custom among the Russian peasants, when a woman dies in the beginning or middle of pregnancy, to put clothes in the coffin for use, in case the woman should deliver herself at the expiration of her full term.

212 CLINTON STREET.

Progress of Medical Science.

Therapeutical Effects and Use of Diuretin. — Dr. Pawinski, of Warsaw, has published a paper on diuretin, or sodio salicylate of theobromine. The drug's therapeutical action was carefully studied by him in a number of cases, of which eleven are adduced with minute details, the series including mitral insufficiency with stenosis, aortic insufficiency, myocarditis and fatty degeneration of the heart, and parenchymatous nephritis. The principal corollaries deduced by the author from his clinical observations may be condensed somewhat as follows: 1. Diuretin does not possess any direct regulating action on the cardiac innervation. Still the drug can remove cardiac arrhythmia in an indirect way—namely, through increasing the secretion of urine, decreasing œdema, and generally relieving such conditions as are apt to interfere with the heart's work. In this regard the remedy proves to be identical with caffeine, which, as Dr. Pawinski's researches have shown, is similarly void of the well-known regulating properties possessed by digitalis. 2. Diuretin increases the arterial tension, which is due to its augmenting the cardiac energy, as well as to stimulating the vaso motor apparatus. The increase, however, is not considerable. At all events, in this particular diuretin is inferior to caffeine, and by far so to digitalis. 3. The sodio-salicylate is undoubtedly endowed with a diuretic action. The increase in the secretion of urine is sometimes very striking, the daily quantity of urine occasionally rising up to five or even six litres. As a rule, the effect becomes pronounced in three or four days after the beginning of the administration, but in some cases the secretion distinctly increases even since the second day (after the patient has ingested a few one-gramme doses of the remedy). As in the case of caffeine, the diuretic action of theobromine is dependent in the first place upon the drug's influence on the vascular system, and in the second upon its intensifying the secretory functions of the renal epithelium. 4. Diuretin is apt to produce an exciting action on the nerve system, which effect is especially manifest in irritable or nervous subjects. In such persons the drug may give rise to general restlessness, tremor of the whole body, insomnia, headache, and aural noises. In old people the remedy may occasionally induce drowsiness. 5. Speaking generally, in chronic diseases of the cardiac muscle diuretin gives better therapeutical results than in cases of organic valvular lesions of the heart or aorta. Still it can prove of excellent service in certain cases of (*a*) mitral incompetence with disturbed compensation in which the patient cannot tolerate digitalis, or in which the latter loses its action; (*b*) aortic valvular disease with increased arterial tension in which digitalis and caffeine are badly borne by the patient; (*c*) valvular mischief associated with intense irritability of the nervous system. In renal affections the therapeutical effects of diuretin are less satisfactory than in the preceding groups of cases. 6. The drug should be given in one-gramme doses, repeated four or five times daily. Sometimes even three grammes a day prove to be sufficient to secure a profuse diuresis. In such cases where a six-days' trial of the drug fails to make any impression on the secretion of urine, a further administration is useless. In some patients even small doses may cause some nausea and vomiting in the beginning; later on, however, the phenomena vanish simultaneously. 7. The best mode of administration is that in solution. The following formula may be used:

℞. Theobromini sodio-salicylici ..... 4 or 6 parts.
Aquæ menthæ piperitæ..... 100.0 parts.
Aquæ destillatæ..... 50.0 parts.
Syrupi simplicis..... 10.0 parts.
M. D. S. To take two spoonfuls every two or three hours.

8. On the whole, theobromine's action resembles that of caffeine. Still the author's clinical experience justifies him to lay down a general rule, and the effect that in cases of an adynamic character caffeine should be resorted to; while in those with predominating erethysm the theobromine salt should be preferred.—*The Provincial Medical Journal.*

Lavage of the Stomach in Cases of Toxic Poisoning. —Experiments carried out by Hitzig, of Halle, have shown that after the subcutaneous injections of morphia in dogs, as well as in human beings, the drug very rapidly makes its appearance in the stomach (*The Medical Press*). For example, when the contents of the stomach have been removed by the stomach-pump, within one or two minutes after an injection, traces of the drug have been found in the gastric contents, and the presence of the drug in that organ probably in this way accounts for the emetic effects so frequently observed in patients after such injections. The result of these experiments goes to show that about one-half of the quantity of the drug injected may be removed by lavage. But if an hour or so be allowed to elapse before lavage is carried out it has been found that the drug has been reabsorbed. Somewhat ingeniously the attempt has been made by Alt to ascertain whether the poison of venomous snakes could be got rid of by these means, and, so far, the experiments in this direction have been satisfactory in proving the utility of the method. Doses of snake poison injected subcutaneously into dogs were rapidly fatal to those animals in which nothing was done, but the same doses were recovered from when lavage of the stomach was carried out for about an hour after the injections. It would seem, therefore, that one of the first steps to take in case of snake-poisoning is to freely wash out the patient's stomach. The difficulty, however, of this treatment would consist in having the stomach-pump handy, and

the opportunity of applying it early enough to secure the best effects from its use. To be of service, not more than a few moments, at the outside, should elapse before it is used—a practical impossibility in the majority of cases of snake-poisoning, unless, indeed, the stomach-pump came to be regularly included among the outfit of persons travelling in districts in which such contingencies are known to occur.

The Action of Cold and Warmth on Muscular Fatigue.—Following up Professor Mosso's researches on the pathology of fatigue, Dr. Patrizi contributes to the journal of the Royal Academy of Medicine of Turin the results of a series of experiments by way of determining the action exerted by cold and warmth on the fatigue of the human muscle. The experiments were made by means of the "ergograph" (Professor Mosso's instrument), and consisted in the execution of a given piece of work—the lifting of a weight by the middle finger of the right hand, either by successive voluntary contractions or by contractions induced by electric irritation. The experiments, moreover, were conducted always at the same hours of the day, and comparison was made of the several tracings which were obtained while the forearm was kept in a bath of hot or cold water. The range of temperature within which the muscles act in executing a piece of work presents no appreciable alteration and is very wide—from 46° to 15° C. This fact Dr. Patrizi recognizes as "providential," seeing the different temperatures at which the muscles of the arm have to undergo fatigue in the ordinary conditions of life. The net result of the experiments goes to prove that with cold the work of the muscle rapidly diminishes—so much so as to become one-fourth of the normal at 15° C., and fifteen times less than the normal at 10° C. On the other hand, above 46° C.—that is, between 46° and 47° C., the maximum limit of supportable heat—work undergoes a slight but constant diminution in all individuals. To explain this fact, confirmed as it is by other observations—a fact, moreover, not to be attributed to the dilatation of the vessels effected by heat and to consequent circulatory disturbance, because otherwise it would be manifested even at temperatures below 46° C.—Dr. Patrizi contends that the blood in the heated muscle is no longer capable of histological exchange, and that the toxic products of fatigue act more energetically on the muscle at high temperatures.—*The Lancet.*

The Spleen in a New Rôle.—The unfortunate spleen has always been the butt of transcendental suggestions and speculations in respect to its functions. Just in the same way as every ophthalmic surgeon seems to think that he ought to invent a new ophthalmoscope, so every physiologist—and the infection appears now to have spread to pathologists—seems to be impressed with the belief that he is not doing his duty in his generation unless he makes the functions of the spleen the subject-matter of some investigations. What an attraction always does environ a mystery? The poor spleen has a mystery all to itself! By no will of its own it finds itself "put away" in the abdomen, with a most uneasy, restless organ for its companion—the stomach. But nobody has ever been able to find out what it does, or what it is there for. The consequence is that the spleen has always been the subject of unenviable gossip, and because it happens to have the habit of "distending" after the stomach becomes loaded with food, and has large arteries and veins, the idea has been arrived at that it must be a sort of dressmaking and millinery establishment for the red blood-cells, which feel somehow compelled to pay it a special visit during the feeding times of the day. But a new function has been found for the spleen. We are now told that the organ is a necessary factor in the production of immunity from infectious disease. Guinea-pigs, for example, from which the spleens had been removed, were found to become permanently incapable of being rendered immune to the virus of tetanus. Hence the idea is that the spleen becomes the store-house of the various antitoxines produced during the course of the infectious diseases. In other words, we are asked to assume now that the organ has another department in its vast establishment, namely a chemical laboratory, with many poisons, all labelled and ready for use, and that when any impertinent microbes pay it a visit, the special antitoxic bottle is taken down, and the spleen gives them a dose of poison, just in the same way as a chemist poisons the venerable pug-dog of his wealthy customer.—*Medical Press.*

Urogenital Blennorrhœa in Children.—In the *Journal of Cutaneous and Genito-Urinary Diseases*, July, 1893, Dr. Henry Koplik has a paper upon this subject, with the following suggestions as to treatment. New methods of procedure, as the use of thalin, iodoform, bougies, injections, silver applications, have been tried by the author with the same success that others have obtained. They fail to shorten the course of the disease in any way. The disease drags on six, eight, or even twelve weeks. The following course has been adopted in all cases, on the principle that the prolonged discharges from the parts are aided by the anatomical nature of the vagina and os uteri. The parts being cleansed with 1 to 5,000 sublimate, externally, a Tuttle urethral speculum is introduced into the vagina, and the canal is thoroughly douched with the sublimate, 1 to 5,000. The parts are then dried with a uterine applicator and cotton, and a ten per cent. solution of nitrate of silver is carried upon a cotton applicator into the vagina up to the cervix, and the parts thoroughly painted with the same. The vagina is again douched with 1 to 5,000 sublimate, and the speculum withdrawn. The nitrate of silver is first applied daily, then every other day. In a few days the discharges cease to be profuse. In acute cases the first few applications cause some bleeding, owing to erosions in the vagina. But this ceases after a time. The urethra in girls is so small, and the treatment of it by present methods causes so much pain, that it is better to let it entirely alone.

Pathology of Paralysis Agitans.—Dr. Ketscher has published a paper dealing with this much disputed subject. The cases of paralysis agitans, with reference to their pathological anatomy, are divisible into two classes—those in which the examination has furnished negative results, and those in which various changes have been found in the nervous system, such as hyperplasia of the connective tissue and neuroglia of the spinal cord, alterations in the nervous tissue itself and vascular changes. Similar changes have been described as occurring in the medulla and pons. Three cases of undoubted paralysis agitans have been investigated by Ketscher. The nervous system, central and peripheral, was examined, and in all three cases changes were found in both regions. The nervous structures showed atrophy, the ganglion-cells of the brain were deeply pigmented and altered in form, the nerve fibres, both in the peripheral nerves and in the spinal cord, were degenerated and had in some instances disappeared, while the muscular fibres were also atrophied or degenerated. The neuroglia was thickened, especially around the vessels, and mostly in the posterior and lateral columns. The vessels also were altered, their walls thickened, and there were miliary aneurisms and small hemorrhages present. Similar changes, but slighter in degree, were found as senile changes in patients not the subjects of paralysis agitans. Ketscher concludes, with Borgherini and others, that paralysis agitans is only the expression of an extreme and premature senility of the nervous system, and he is of the opinion that the primary changes are in the vessels, those in the nervous structures being secondary.—*Journal of the American Medical Association.*

Mineral Baths during Normal and Pathological Menstruation.—Dr. Makawejew gives his experience with mineral baths during menstruation. His position as resident physician at the baths of Staraja Russa in Rus-

sia, which resemble those of Kreuznach in character, has given him opportunities to study this question. (*Boston Medical and Surgical Journal*) In common with all bath physicians, so-called, he looked upon the onset of menstruation as a signal for ceasing the administration of baths, but has gradually, as a result of his experience and experiments, come to doubt the truth of the theory that they are harmful, and even to believe that they are of distinct benefit at the time of the catamenia. Experimentally, he shows that saline or mud baths at blood heat cause a rise of temperature at the outside of the body, and a lowering inside; warmer baths cause a rise of both external and internal temperature, the first more than the last, and colder, a fall of both temperatures, especially the inner. The explanation is that the saline or mud-baths act as an irritant to the skin, cause a dilatation of the superficial blood-vessels, and hence a diminished quantity of blood in the internal organs. The result of this would be, in the case of menstrual disorders, a diminution of the amount of blood in the uterus, hence a diminished rather than an increased menstrual flow. Practically, he found this to be the case. To sum up his results, which he gives in a good deal of detail, he treated 149 patients with baths during menstruation. Of these 115 menstruated regularly and the regularity was not affected; 34 were irregular and became regular during the treatment. Where the catamenia lasted the normal time there was no effect; where it was prolonged (in 69 cases), it was shortened by the treatment. In cases of metrorrhagia the amount was usually materially diminished. Dysmenorrhœa was present in 90 cases; under the influence of the baths it disappeared in 60, and in 28 it was lessened. There was general nervous disturbance and hysterical condition in 87 cases, which disappeared under the treatment in 58, and was much less in 29. The importance of these observations from a gynecological point of view is evident, and the author claims that we have in baths rightly administered a means of controlling uterine congestion and favorably influencing the symptoms which are caused by it.

Extirpation of the Uterus without Ligatures.—Dr. Landau discards all ligatures and sutures in this operation, and trusts entirely in place of them to the action of pressure forceps. All instruments are entirely of metal, and they are previously sterilized by boiling. The crumbly parts of the cancerous mass are first removed with the curette, and the parts occupied by them are energetically rubbed with a three per cent. solution of carbolic acid. During the operation nothing but boiled water rendered alkaline by soda is used for irrigation. A careful examination must be made to determine whether the uterus can be readily drawn down, or whether it is fixed by any morbid process to its normal level. If the former, the operation is easy, and generally completed in a very short time. If the uterus is fixed, however, the paracervical tissues must be separated from their attachments; care must be taken not to attempt too forcibly, either by pressure from above or by dragging by forceps from below, to bring the uterus down, as the tender broad ligament may easily be torn through, and fatal hemorrhage set up, or an abscess burst. The freed uterus must be left in position, and the operation must be proceeded with, making use of a large number of small forceps. The operator pushes his finger behind the ligament, and the assistant in front of it, and in this way a path is made for the passage of the forceps without danger to any important part. If the fixation is greatest on one side it is best to commence with the diseased one. The operator advances upward step by step, so that in case of complication by ovarian tumor or tubal cysts, these gradually come into view, are punctured or incised to lessen their bulk, lateral forceps are then put on, and the parts cut away. In case of difficulty in bringing the parts all into view, the speaker proposed to remove the uterus piecemeal until it was all got away. The after-treatment was quite simple, and alike in all cases. The forceps were removed after from thirty-six to forty-eight hours, but without altering the position of the patient. While the forceps remain on it is best to leave a catheter in the bladder. If the pain is great, morphia may be given in sufficient doses. After removal of the forceps a vaginal douche may be cautiously given thrice daily, weak disinfectant and deodorant solutions being the best, such as potass. permang., sod. bibor., or boric acid and salicylates. On the third day the secretion from the stump increases, and is frequently mixed with shreds of tissue, and ceases then very gradually. He believes that the dangers of hemorrhage and sepsis are diminished by this method of operating, and that cases that are positively "inoperable" by the ligature method can be treated successfully in this way. He has only seen secondary hemorrhage in one case, in which the forceps were removed at the end of twenty-four hours. If the forceps are opened carefully, and so removed, there is no danger of injuring the parts. He has seen hemorrhage in two cases after the seventeenth day, but, as he says, hemorrhage such as that might equally easy come on if ligatures were used. As showing the rapidity with which the operation could be completed, he stated that he had done it once in four minutes, and once in six and a half minutes, in each case without undue haste.—*Medical Press.*

Sarcoma of Tonsil Removed by External Incision.—At a late meeting of the Clinical Society of London (*The Lancet*) Mr. Raymond Johnson read the notes of a case of lympho sarcoma of the tonsil removed by external incision, with preliminary ligature of the external carotid artery. The patient was a woman, aged fifty-three, whose symptoms were of about six months' duration. The growth, which occupied the position of the left tonsil, was oval in shape and measured one inch and a half by seven eighths of an inch in its two diameters; its surface was covered with short papillary processes. A mass of soft glands was situated below and behind the angle of the jaw, and other smaller glands lay along the posterior border of the sterno mastoid. Notwithstanding the somewhat extensive nature of the glandular infection it was decided to operate. This was done on June 20, 1892. The incision extended from the lobule of the ear to the level of the hyoid bone, and from it an incision was carried to the extent of one inch along the anterior border of the sterno mastoid. The mass of glands was easily dissected out and then a silk ligature was applied to the external carotid artery below the origin of the lingual. The lateral wall of the pharynx was next freely exposed and the primary growth was excised, together with a margin of healthy tissue around it, by means of scissors. The hemorrhage was very trivial. The skin incision was sutured with silk and drained at the lower angle, no attempt being made to close the opening in the wall of the pharynx. Rectal feeding was adopted for two days after the operation. The patient progressed without a bad symptom except some suppuration in the lower part of the wound. On July 14th, the enlarged glands behind the sterno mastoid were excised through an incision along the posterior border of the muscle. The patient was discharged on July 23d. In December a small gland was excised from beneath the scar behind the jaw, and other very small ones were felt in both sides of the neck. The patient's general health had much improved and there was no recurrence in the pharynx. Reference was made to the other modes of removing tumors of the tonsil. The incision made was very similar to the one made by Cheever and Golding Bird. It was urged that the application of a ligature to the external carotid artery, which added very little to the difficulty or length of the operation, was a more satisfactory mode of dealing with hemorrhage than such methods as the performance of a preliminary tracheotomy or the removal of the growth with the cautery. The patient, who was exhibited eight months after the operation, was in good general health and free from recurrence in the mouth, but there were some slightly enlarged glands in both sides of the neck.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

New York, September 2, 1893.

POISONING BY DIACHYLON LEAD PLASTER.

IN a recent issue of the *British Medical Journal*, Dr. F. M. Pope narrates the history of two cases, in both of which a fatal result supervened. Poisoning by this compound is very unusual, but it seems that in some of the English manufacturing towns it is credited with the power of preventing conception, and with emmenagogue properties, and is used to procure abortion. Dr. Pope's first case was that of a woman, aged thirty-three, who complained of sharp pain in the right iliac region, constipation, and vomiting after eating. Medical treatment relieved these symptoms, but the abdominal soreness remained with a tendency to costiveness. The skin and conjunctivæ became yellow and the tongue coated. She passed six weeks without menstruating. A blue line appeared on the gums, and the muscles of the hands grew weak and tremulous. The reflexes were normal but weak. There was no sensory disturbance. The patient drank water from a faucet connected with the city pipes.

A diagnosis of lead-poisoning was made and potassic iodide ordered. Three days later she grew comatose and died. The autopsy showed the bowels to be contracted, but nothing else could be noted. The brain appeared perfectly healthy. No positive clew could be found as to the source of the lead. The water was tested with negative results.

Quite a long time after it was learned that the woman had told someone that she had been advised to take diachylon for the purpose above named.

In about two years a second patient came under observation. She was twenty-two years of age and anæmic. The skin and conjunctivæ were of a yellowish tint. She seemed of weak intellect, though not formerly so; had a fatuous expression, and would not speak above a whisper. She complained of pain in abdomen, principally in the right iliac fossa, and attributed her symptoms to a miscarriage which occurred in May last. Her health before her marriage, three years since, was good. She had had two children, both of whom died in infancy, and two miscarriages. At the last, in May, 1892, she lost a good deal of blood, and since that time had been suffering from pains, and had had no return of menstruation. There were no abnormal signs in the lungs, heart, or abdominal viscera, and no signs of syphilis. There was pain on pressure over the hypogastrium. The bladder was distended. On vaginal examination nothing abnormal was found. The rectum was loaded with fæces. The urine (specific gravity 1015) was of a dark reddish color, but contained no blood, albumin, bile, or sugar. The limbs were weak, but she could move them all; the deep reflexes absent; sensation was unimpaired. The bowels were relieved by enema, and the urine was then passed naturally. After remaining in about the same condition for a week, she had an epileptiform convulsion on the night of August 8th, six days after she was first seen. The tongue was bitten; the bladder found again distended. On the morning of August 9th there was complete loss of power in the arms and legs, and fæces were passed involuntarily. The condition was thought to be due either to tuberculous meningitis or a cerebral tumor. On August 10th she had several more convulsive attacks, was continually crying out, and rolling her head from side to side. The paralysis had extended to the diaphragm; this caused suspicion that her condition might be due to peripheral neuritis, and inquiry was made from the friends as to the possibility of diphtheritic poisoning, but no history of sore throat could be elicited. The faradic current was applied to the diaphragm, but she died at 8.45 A.M., on August 11th.

At the autopsy the intestines were found contracted and contained considerable yellowish, sticky fluid. The internal generative organs were normal, and no corpus luteum was found in either ovary. Some weeks before her death she acknowledged having taken diachylon, and, furthermore, that she had done so many times previously, with the end in view of inducing abortion.

These cases are of interest, not so much from their symptomatology as from the fact that death was caused by a drug not generally given internally; but the circumstances surrounding these two cases unquestionably suggests its frequent use among the women of that locality.

Dr. Pope makes an interesting suggestion as to how diachylon came to have the reputation which led to its internal employment. Diachylon, he reminds us, is a plaster as old as Galen's time, and older, but it had not then its present simple constitution. It contained, in addition to litharge, marshmallow, linseed, and fenugreek, and may have had this composition till comparatively late times. Hippocrates recommends lint-seeds among other things as an emmenagogue, and Pliny and many others say that fenugreek is an ecbolic. Old superstitions die hard. Is it possible that we are dealing with one dating from the time when diachylon contained these drugs, and that it then had a reputation as an ecbolic which has been transferred to its successor in the pharmacopœia? There is another plaster mentioned by Paulus Ægineta similar to diachylon, containing marshmallow, linseed, fenugreek, and in addition rosin, tears of ivy, and turpentine, but no litharge. Is it possible this was also known as diachylon, and, being comparatively harmless, was used as an emmenagogue?

The Eyes of College Students.—The statistics of the senior class at Yale College this year, furnished by the class history, raise the question as to the effects of hard study on the eyes. Out of a class of 185 there are 54 who wear glasses, and of these 25 have taken to their use since entering college. The average age of the class is about twenty-two years, and yet nearly one third of them are compelled already to reenforce their eyes.

"THE CITY OF MAGNIFICENT HOSPITALS."

Much comment has been excited by our modest portrayal of New York as the "City of Magnificent Hospitals." Some of our English brethren feel alarmed over such prodigious displays of philanthropy. The *Medical Press and Circular* in particular holds out this warning. It says:

"An American contemporary proudly asserts that New York might well be called the 'City of Magnificent Hospitals.' The reason which has led to this outburst of praise is the fact that three new large hospitals are in process of erection in the city, while a fourth is shortly to be commenced. No other city in the New World, we are informed, 'can compare in extent with the palatial character and the scientific completeness of its hospital buildings,' and 'when these various new structures are completed they will form, taken in connection with the other institutions, a magnificent tribute to human philanthropy and medical science.' But it is quite possible to have too much of a good thing, even of philanthropy. What have the general practitioners, or, as they are called in the States, 'physicians,' to say upon this subject? Can they possibly hail with acclamation the foundation of four new hospitals in New York, when the establishment of each institution of the kind must conceivably reduce the number of their private patients? New York may be a 'city of magnificent hospitals,' but whether the policy has been a sound one which has made it so is entirely another matter. Upon the whole, quite possibly the profession generally would be prepared to dispute the expediency of all this lavish expenditure upon hospitals; both on professional as well as on public grounds, the facilities for charitable relief should be kept within due bounds."

The *Press* has only expressed sentiments which have appeared in these columns. But a good many rich men like to amuse themselves and exploit their wealth and generosity by supporting hospitals. We do not know of any corporation which has ever refused their money, or of any physician who has declined to accept service with the managing boards. And so we do not see but that the building of great hospitals will go on, until at last there is room for almost every one. Then there will perhaps be a reaction, and the public will gradually learn that it is best to pay for what they get, even if it is a surgical operation.

A TWICE-TOLD TALE.

Every now and then there is a recrudescence of learned articles regarding the antiquity of syphilis. Sometimes the savant points his learned finger toward Columbus, and describes the curse as originating among the aborigines of this country. At other times he sets his face toward the East, and then we read painful quotations from Job and the Psalmist, with admiring comments on the wisdom of Moses. A new impulse to prehistoric syphilography has been given by the book of Dr. Buret on "Syphilis in Ancient Times." Dr. J. T. Jells gives us some interesting facts taken from this treatise (*Journal of the American Medical Association*). Dr. Buret has greatly enlarged the list of the afflicted heroes of the past, being helped to his knowledge by the later discoveries of archæologists. We learn that syphilis antedates the year 1921 B.C., that being the time of Abram; the story we are told is that Sarah had the disease, and gave it to Pharaoh when the patriarch and his wife visited Egypt. Nimrod, the mighty hunter, was also a victim, as was one of his friends. Coming back to the scriptures we are told that David was surely a victim of syphilis, and that epidemics of the disease prevailed among the Israelites. The Chinese are credited with having been the first at nearly everything, and it is affirmed that syphilis prevailed among them 2500 years B.C. But more than all this, syphilis is accredited by Buret to prehistoric man, and the disease has been recognized on the bones of men who died 60,000 years ago!

All this is, as a contemporary daily is fond of saying, mighty interesting, the only trouble being that it isn't so. The learned gentlemen are all dealing in speculations which have no value when the evidence is strictly weighed.

THE TONGUE IN INFLUENZA.

Faisans recently made an interesting communication to the Société médicale des Hôpitaux, concerning the tongue in grip. Its special characteristic is an opaline tint of bluish white, sometimes uniformly distributed and again appearing in patches. This porcelain appearance of the tongue is often the first definite sign of grip, and accompanies the vague malaise that precedes the disease. It always appears during the first two or three days. As long as the condition is present, the patient is by no means well, though recovery may be apparent. Complications may arise as long as the opaline tint remains. The tongue is not altered in form or dimensions, nor is it ever dry unless some phlegmonous inflammation is imminent or has already begun. If there is a catarrh of the digestive tract, and the tongue becomes heavily coated, the opaline tint is still visible about the borders, and may show through the coating in places. Cathartics may help clear up the furred tongue, but its characteristic porcelain effect remains. In pneumonia complicating grip, the tongue dries up without effect upon the opaline tint upon its borders. In a case of supposed meningitis in a child, the peculiar appearance of the tongue served to establish the diagnosis of grip, a diagnosis verified by subsequent events. Sometimes there is lingual desquamation, as in scarlet fever.

Ustilago Maidis.—Blair (*Therap. Gaz.*, May, 1893) draws attention to ustilago maidis (maize ergot) as a valuable drug in obstetric practice, and one which far excels ordinary ergot as an aid in tedious labor. It is prepared from maize affected with the disease known as "corn smut," and has been introduced into practice in the form of a fluid extract. The author has tried this preparation in a dozen cases of labor, with in most cases satisfactory results. The dose employed was from twenty to thirty minims. His general conclusions are as follows: (1) In those cases in which the pains were continuous, the effect of the drug was to make them intermittent and more easily borne. (2) Where natural labor pains were present and the extract was administered, the uterine contractions were increased in strength and labor hastened. (3) The effects were more favorable after considerable dilatation of the cervix had taken place, though the action of the drug was tested at all stages. In no instance were any bad effects produced.

News of the Week.

Yellow Fever.—The third case of yellow fever has occurred at Brunswick, Ga., but it is not believed that the disease will become epidemic, although many people have left the town in anticipation of that event. No cases have occurred at Port Tampa, which was recently visited by an infected ship.

A Definition of Temperance.—At the recent Anti-alcohol Congress held at The Hague, a number of speakers contended for a moderate use of alcohol, defining moderation as the consumption of an ounce to an ounce and a half in the twenty-four hours.

Dr. Hiram Hubbs, of Amsterdam, N. Y., died recently at the age of seventy-three. He was graduated from the Albany Medical College, but soon gave up the practice of medicine and devoted his energies to farming.

Microbes in Dust.—Microscopic examinations of dust from the streets of Naples have shown the presence of immense numbers of micro-organisms, among them the bacilli of tetanus and of tuberculosis.

Pan-American Medical Congress.—The following papers are to be read in the several sections:

Section on Diseases of the Mind and Nervous System.—Formal Address, by Dr. C. H. Hughes, Executive President of the Section, of St. Louis, Mo.; "The Gangliated Nervous System and some of its Diseases," by Dr. Charles K. Mills, of Philadelphia, Pa.; "The Traumatic Psychoneurosis, its Relations to Paranoia, Epilepsy, and Paretic Dementia," by Dr. J. G. Kiernan, of Chicago, Ill.; "The Urine in Sexual Neurasthenia," by Dr. Charles L. Dana, of New York, N. Y.; "Suppurative Meningitis and Myelitis, with Exhibition of Specimens," by Dr. Græme M. Hammond, of New York, N. Y.; "The Disease of Inebriety and its Treatment," by Dr. T. D. Crothers, of Hartford, Conn.; "Chorea," by Dr. Charles Henry Brown, of New York, N. Y.: "Study of the Temperature in Twenty-five Cases of General Paralysis of the Insane," by Dr. Frederick Peterson, of New York, N. Y.; "The Present Status of Infantile Cerebral Palsies," by Dr. Frederick Peterson, of New York, N. Y.; "The Successful Management of Inebriety without Secrecy in Therapeutics," by Dr. C. H. Hughes, of St. Louis, Mo.; "Erotopathia: Morbid Erotism," by Dr. C. H. Hughes, of St. Louis, Mo.; "The Medical Treatment of Insanity," by Dr. Edward C. Mann, of Brooklyn, N. Y.; "Address of Welcome" (in Spanish), by Dr. William A. Hammond, of Washington, D. C.; "Where the New-born Baby Learned to Suck," by Dr. C. A. F. Lindorme, of Atlanta, Ga.; "Treatment of Nervous Diseases in Sanitariums," by Dr. James K. King, of Watkins, N. Y.; "The Influence of Alcohol upon the Human Powers and Constitution," by Dr. T. L. Wright, of Bellefontaine, O.; "The Treatment of Cerebral Hemorrhage," by Dr. D. R. Brower, of Chicago, Ill.; "Neuro-angio Paralysis and its Relation to Paretic Dementia," by Dr. Frank C. Hoyt, of Clarinda, Ia; "Civil Service in American Hospitals for the Insane," by Dr. S. V. Clevenger, of Chicago, Ill.; "La Renguera," by Dr. Daniel Guiterrez y Arango, of Cali, Cauca, Colombia; "Paralisis Espastica Cerebral de los Adultos," by Dr. Manuel Carmona y Valle, of City of Mexico, Mexico; "On the Prognosis of 'Railway Spine,'" by Dr. F. X. Dercum, of Philadelphia, Pa.; "The Nervous Symptoms of Storms," by Dr. Curran Pope, of Louisville, Ky.; "A Peculiar Type of Vaso-motor Neurasthenia (The Pulsating Disease), with Report of and Operation for the Same," by Dr. Charles L. Dana, of New York, N. Y.: "Curability of Inebriety," by Dr. J. G. Reed, of Elmwood Place, O.; "Nutrition against Stimulation," by Dr. W. H. Maxon, of St. Louis, Mo.

Papers by Dr. William A. Hammond, of Washington, D. C.; Dr. Theodore D. Diller, of Pittsburg, Pa.; Dr. E. C. Seguin, of New York, N. Y; Dr. S. Weir Mitchell, of Philadelphia, Pa.; Dr. E. C. Spitzka, of New York, N. Y.; Dr. O. T. Sherman, of Boston, Mass.

Section on Diseases of Children.—"The Most Successful Method of Treating Croup," by Dr. J. O'Dwyer, of New York, N. Y.; "The Teaching of Hygiene in Colleges and Public Schools," by Dr. F. Forchheimer, of Cincinnati, O.; "Clinical Aspects of Infant Feeding," by Dr. E. P. Davis, of Philadelphia, Pa.; "Clinical Notes of Eruptive Fevers in Southern California," by Dr. W. A. Edwards, of San Diego, Cal.; "Infant Feeding," by Dr. T. M. Rotch, of Boston, Mass.; "The Time and Mode of the Introduction of the Exotic Diseases of Children into America," by Dr. J. Lewis Smith, of New York, N. Y.; "Physical Training of Public-school Children," by Dr. J. Gardiner Smith, of New York, N. Y.; "Palmus," by Dr. L. C. Gray, of New York, N. Y.; "Enteroclysis in Intestinal Diseases of Children," by Dr. E. E. Graham, of Philadelphia, Pa.; "Bacteriological Diagnosis of Diphtheria," by Dr. H. C. Ernst, of Boston, Mass.; "Aphasia in Children," by Dr. F. Peterson, of New York, N. Y.; "On Milk," by Dr. Henry D. Chapin, of New York, N. Y.; "The Race Factor in Gastro-intestinal Disease," by Dr. J. W. Byers, of Charlotte, N. C.; "The Treatment of Empyema in Early Life," by Dr. A. Brothers, of New York, N. Y.; "A Contribution to the Knowledge of Acute Primitive Entero colitis during Low Infancy," by Dr. Joaquin L. Dueñas, of Havana, Cuba; "The Production of Cow's Milk Designed for Infant Feeding," by Dr. Henry L. Coit, of Newark, N. J.; "The Proper Mode of Preventing and Treating Diphtheria, Based on Recent Discoveries Relating to its Etiology and Pathology," by Dr. J. Lewis Smith, of New York, N. Y.; "The Normal Præcordia in Infancy and Childhood," by Dr. H. B. Whitney, of Denver, Col.: "Intestinal Parasites Observed in the Island of Porto Rico," by Dr. Antonio Amadeo, of Manuabo, Porto Rico; "Immediate Percussion among Children," by Dr. Olinto, of Porto Algre, Brazil; "Feeding of Children in Cuba during Infancy," by Dr. Joaquin L. Dueñas, of Havana, Cuba; "Pertussis as it Exists in the Rocky Mountains," by Dr. John M. Keating, of Colorado Springs, Col.; "Types of Gastro intestinal Disease Prevalent in New York," by Dr. Floyd M. Crandall, of New York, N. Y.; "Insane Disorders of Childhood," by Dr. J. Madison Taylor, of Philadelphia, Pa.; "Cirrhosis of the Liver in Children," by Dr. William A. Edwards, of San Diego, Cal.; "The Artificial Feeding of Children in Mexico," by Dr. J. Ramon Icasa, of City of Mexico, Mexico.

Paper by Dr. J. B. Deaver, of Philadelphia, Pa.

Section of Pathology.—"Abscess of the Liver," by Dr. James E. Reeves, of Chattanooga, Tenn.; "Notes on Three Years' Work in the Pathological Laboratory of the Charity Hospital of New Orleans," by Dr. Henry Dickson Bruns, of New Orleans, La.; "Influenza," by Dr. Ramon Guiteras, of New York, N. Y.; "A Bacteriological Observation on the Waters of the Harbor of Havana," by Drs. Acosta and Grande, of Havana, Cuba; "Pathological Histology of Yellow Fever," by Drs. Acosta and Grande, of Havana, Cuba; "Investigations Concerning Malaria," by Drs. Coronada and Madau, of Havana, Cuba; "Bacteriological Studies in Havana," by Dr. Davalos, Havana, Cuba; "Investigations upon the Carbuncle in Cuba," by Dr. Coronado, of Havana, Cuba; "Observations on the Anti-rabic Treatment of Pasteur," by Dr. Acosta, of Havana, Cuba; "Etiology of Cancer, with Especial Regard to the Protozoa Parasites of Cancer," by Dr. Allen J. Smith, of Galveston, Tex.; "Contribution to the Study of Cancer," by Dr. Wernicke, of Buenos Ayres, Argentine Republic; "Medical Geography of Porto Rico," by Dr. A. J. Amadeo, of Maunabo, Porto Rico; "Yellow Fever of the Creoles and the Negroes," by Dr. A. J. Amadeo, of Maunabo, Porto Rico; "Theories of Inflammation," by Dr. José Torres Matos, of Havana, Cuba; "L'État de Hyperexcitabilité du Nerf phrénique dans le Beriberi," by Dr. J. B. Da Lacerda, of Rio de Janeiro, Brazil; "Paludismo," by Dr. Antonio José Amadeo, of Maunabo, Porto Rico; "Pathology at the Institution for Feeble-minded Children, at Elwyn, Pa.," by Dr. Henry W. Cattell, of Philadelphia, Pa.; "The Epithelio-genetic Origin of Cancer," by Dr. Joseph McFarland, of Philadelphia, Pa.; "Cancer," by Dr. Wernicke, of Buenos Ayres, Argentine Republic (Formal Discussion, with Professor Allen J. Smith as Co-referee); "Cancer," by Dr. Joshua M. Van Cott, of Brooklyn, N. Y.; "Cancer," by Dr. Joseph McFarland, of Philadelphia, Pa.; "Yellow Fever," by Drs. Acosta and Grande, of Havana, Cuba (Formal Discussion, with Dr. A. J. Amadeo, of Porto Rico, as Co-referee); "Practical Demonstration of the Methods in Pathological Histology," by Dr. James E. Reeve, of Chattanooga, Tenn.; "Practical Demonstration of the Methods in Photography Applied to Pathology," by Dr. William M. Gray, Army Medical Museum, Washington, D. C.; "Practical Demonstration of Methods in Bacteriology," by Dr. J. J. Kinyoun, U. S. Marine Hospital Service, Washington, D. C.; "The Third Blood Corpuscle as a Pathological Product," by Dr. R. L. Watkins, of New York, N. Y.; "On Cholera," by Dr. Herman M. Briggs, of New York, N. Y.; "Pathology of Pelvic Inflammatory Trouble," by Dr. Joseph Price, of Philadelphia, Pa.

Papers by Dr. William Henry Welch, of Baltimore, Md.; Dr. W. T. Councilman, of Boston, Mass; Dr. E. O. Shakespeare, of Philadelphia, Pa.; Dr. G. F. Nuttall, of Baltimore, Md.; Dr. William Hughes, of Philadelphia, Pa.; Dr. W. J. Carter, of Philadelphia, Pa.

Section on Therapeutics.—"The Treatment of Scarlet Fever by Chloral Hydrate," by Dr. James C. Wilson, of Philadelphia, Pa.; "A Plea for Physiological Remedies," by Dr. Simon Baruch, of New York, N. Y.; "Treatment of Chronic Catarrh and Allied Conditions of Lowered Hydrochloric Acidity," by Dr. D. D. Stewart, of Philadelphia, Pa.; "The Physiological Actions of Alcohol," by Dr. David Cerna, of Galveston, Tex.; "The Treatment of Neurasthenia, with Special Reference to the Best Cure," by Dr. F. X. Dercum, of Philadelphia, Pa.; "The Advantages of Amorphous Phosphorus over the Officinal Form," by Dr. E. I. Richardson, of Philadelphia, Pa.; "Venesection in Treatment of Engorgement and Dilatation of Right Side of the Heart," by Dr. I. E. Atkinson, of Baltimore, Md.; "The Use of Nitroglycerine in Arterio-sclerosis," by Dr. T. G. Ashton, of Philadelphia, Pa.; Formal Address, by Dr. Hobart A. Hare, Executive President, of Philadelphia, Pa.; "The Philosophy of Therapeutics," by Dr. L. B. Anderson, of Norfolk, Va.; "The Antipyretic Action of Alcohol," by Drs. A. B. Simmons and R. J. Winn, of Savannah, Ga.; "Some Views Regarding the Philosophy of Drug Action," by Dr. J. W. McLaughlin, of Austin, Tex.; "The Treatment of Leprosy," by Dr. Richard H. L. Bibb, of Satillo, Mexico; "The Clinical Import of Kumyss," by Dr. J. Mount Bleyer, of New York, N. Y.; "The Treatment of Exophthalmic Goitre based on Forty-five Consecutive Cases," by Dr. A. D. Rockwell, of New York, N. Y.; "Étude sur un Moyen d'Assurer l'Efficacité du Copaiba dans la Médication suppressive de la Blennorrhagie Uréthrale," by Dr. L. T. C. Lamothe, Port au Prince, Hayti; "Action Physiologique de quelques Plantes Brésiliennes de la Famille des Menespermacies," by Dr. J. B. Da Lacerda, of Rio de Janeiro, Brazil; "Une Plante Convulsivante du Brésil," by Dr. J. B. Da Lacerda, of Rio de Janeiro, Brazil; "Pathology and Treatment of Gout," by Dr. James Tyson, of Philadelphia, Pa.; "Contribution to the Therapeutics of Yellow Fever," by Dr. Pedro Peñuelas, of Havana, Cuba; "Some Points in the Treatment of Uric Acid Diathesis," by Dr. F. E. Stewart, of Watkins, N. Y.; "A Contribution to the Treatment of Diabetes Mellitus," by Dr. Solomon Solis-Cohen, of Philadelphia, Pa.; "The Value of the Bath in some Sthenic Conditions, particularly Typhoid Fever," by Dr. Simon Baruch, of New York, N. Y.; "The Indications which should Govern the Employment of the Several Anæsthetics," by Dr. H. C. Wood, of Philadelphia, Pa.; "Electricity, Its Use in Medicine," by Dr. F. Schavoir, of Stamford, Conn.

Papers by Dr. Edward Randall, of Galveston, Tex.; Dr. Edward Martin, of Philadelphia, Pa.; Dr. Fernando Altamirano, of City of Mexico, Mexico.

Section on Dermatology and Syphilography.—"American Dermatology," by Dr. A. H. Ohmann-Dumesnil, Executive President of the Section, of St. Louis, Mo.; "Lupus, its Excision, with Reports of Cases," by Dr. B. Merrill Ricketts, of Cincinnati, O.; "Glycosuria as an Additional Symptom in the Neurotic Origin of Dermatitis Herpetiformis," by Dr. James M. Winfield, of Brooklyn, N. Y.; "A Statistical Record of Nearly Five Thousand Cases of Small-pox," by Dr. William M. Welch, of Philadelphia, Pa.; "The Treatment of Diseases of the Nails," by Dr. J. V. Shoemaker, of Philadelphia, Pa.; "Primary Dystrophies of the Skin," by Dr. E. Preble, of Cleveland, O.; "Rhinophyma," by Dr. William Gottheil, of New York, N. Y.; "Rhinophyma," by Dr. A. H. Ohmann Dumesnil, of St. Louis, Mo.; "Frambœsia," "Yaws," by Dr. George Edmund Pierez, British West Indies; "The Question of the Communicability of Leprosy," by Dr. Beaven Rake, of Trinidad, West Indies; "Some of the Rarer Tropic Lesions in

Leprosy," by Dr. Beaven Rake, of Trinidad, West Indies; "Beriberi en el Cauca," by Dr. Evaristo Garcia, of Cali, Cauca, Colombia; "Lepra en el Cauca," by Drs. Evaristo Garcia and Adolfo Tenoris, of Cali, Cauca, Colombia; "El Caratea," by Drs. Juan N. Wallis O., and Alfredo Garces y Domingo, of Arboleda, Colombia; "A Case of Recurrent Pruritus," by Dr. A. H. Ohmann-Dumesnil, of St. Louis, Mo.; "On the Etiology of Eczema," by Dr. A. Ravogli, of Cincinnati, O.

Paper by George Holsten, of Brooklyn, N. Y.

Section on Laryngology and Rhinology.—"The Relation of Diseases of the Rectum to Nasal Catarrh," by Dr. W. John Harris, of St. Louis, Mo.; "Electrolysis for the Relief of Certain Morbid Conditions of the Nasal Septum," by Dr. James E. Newcomb, of New York, N. Y.; "Myxosis of the Pharynx," by Dr. W. C. Glasgow, of St. Louis, Mo.; "The Easiest and most Practical Means of making Galvano-cauteries—especially to Turbinate Hypertrophies," by Dr. Arthur G. Hobbs, of Atlanta, Ga.; "The Use of Formate of Soda in Laryngeal Disease," by Dr. E. L. Shurly, of Detroit, Mich.; "The Utility of the Electro-cautery Snare," by Dr. H. W. Loeb, of St. Louis, Mo.; "Reflex Epilepsy from Intra-nasal Disease," by Dr. John O. Roe, of Rochester, N. Y.; "A Case of Angioma of the Nasal Septum," by Dr. Frederick C. Cobb, of Boston, Mass.; "A Case of Elongation of the Epiglottis reduced by Operative Measures," by Dr. Price Brown, of Toronto, Canada; "Some of the Throat Conditions Observed in Gouty Subjects," by Dr. S. Solis-Cohen, of Philadelphia, Pa.; "The Ultimate Prognosis in Neglected Adenoid Hypertrophy," by Dr. D. Bryson Delavan, of New York, N. Y.; "Report of a Case of Myxosarcoma of the Nasal Cavity," by Dr. C. W. Richardson, of Washington, D. C.; "Surgical Treatment of Empyema of the Maxillary Sinus," by Dr. Edward Obejero, Buenos Ayres, Argentine Republic; "Report on Cases of Tubercular Laryngitis treated in Colorado Springs," by Dr. S. E. Solly, of Colorado Springs, Col.; "Sarcoma of Naso-pharynx, with Report of Case," by Dr. James E. Logan, of Kansas City, Mo.; "Alumnol in Diseases of the Throat and Nose," by Dr. J. Mount Bleyer, of New York, N. Y.; "Some Forms of Nasal Reflexes, with Report of Cases," by Dr. S. K. Merrick, of Baltimore, Md.; "Hysterical Aphonia and Deafness," by Dr. E. Fletcher Ingals, of Chicago, Ill.; "Clinical Notes of Cases of Tubercular Ulceration of the Larynx treated by the Krauss Method at the Throat and Chest Clinic of the Emergency Hospital," by Dr. T. Morris Murray, of Washington, D. C.; "Indications and Opportunity for Opening the Mastoid Process," by Dr. Edward Obejero, of Buenos Ayres, Argentine Republic; "On the Treatment of Empyema, with due Regard to Normal Pulmonary Contractibility," by Dr. Dan Millikin, of Hamilton, O.

Papers by Dr. Robert Levy, of Denver, Col.; Dr. W. H. Daly, of Pittsburg, Pa.; Dr. A. C. Wolfe, of Columbus, O.; Dr. G. B. Lawrason, of New Orleans, La.; Dr. Jonathan Wright, of Brooklyn, N. Y.; Dr. John N. McKensie, of Baltimore, Md.; Dr. Charles H. Knight, of New York, N. Y.; Dr. Alexander MacCoy, of Philadelphia, Pa.; Dr. J. C. Mulhall, of St. Louis, Mo.; Dr. Edward O. Clyer, of Buenos Ayres, Argentine Republic; Dr. C. E. Bean, of St. Paul, Minn.; Dr. H. Holbrook Curtis, of New York, N. Y.

Pan-American Medical Congress.—*Hotel Rates and Capacities.*—Hotel Normandie: Two in a room, $4.00; one in a room, $5.00 per day, American plan; accommodation for 100. The Arlington: $4.00 and $5.00 per day; accommodation for 500. Cochran Hotel: $4.00 and $5.00 per day; accommodation for 50 to 75. Wormley's Hotel: $4.00 per day; accommodation for 100. Randall Hotel: $2.50 and $3.00 per day; accommodation for 75 to 100. Willard's and Riggs's: $3.50 to $4.00 per day; accommodation for 400 to 500. Arno: $1.50 to $2.50 for room, European; and $3.00 to $4.00 per day, American; accommodation for 200. Shoreham: $2.00 to $3.00 for room, European; $4.00 to $5.00 per day, American. National Hotel: $2.50 to $4.00 per day. St. James Hotel: $1.00 to $2.00 each; suites, with bath, $3.00 to $5.00 each; and $5.00 to $6.00 for two persons; accommodation for 300. Ebbitt House: $3.00, $3.50, and $4.00 per day; no extra charge for alcove parlors; accommodation for 350.

Dr. George W. Benton, died at his home in Baltimore, of Bright's disease. He was born in Princess Anne, Somerset County, Md., in 1831, and when twenty years of age took his medical degree at the University of Maryland. He was appointed Health Commissioner of Baltimore in 1872. He served two years, and ten years later was again appointed to the place.

The Progress of Medical Science.—In a recent address at the University of Glasgow, Professor McKendrick summed up the results of modern medical research, thus: 1, Thousands of lives saved annually by preventive medicine; 2, greater accuracy in diagnosis, and a sounder knowledge of the natural history of disease; 3, more rational treatment; 4, many diseases caused to pass through their stages more speedily, thus saving time; 5, better means of relieving pain and suffering; and 6, making disease, even when incurable, more tolerable, and at last smoothing the passage to the Elysian Fields.

The Contagiousness of Influenza.—The Government report of an investigation into the influenza epidemic of the past four years, in Great Britain, regards the proof of the contagiousness of the disease as overwhelming, and denies that it is transported through the atmosphere.

The Skull of Sophocles is said to have been found by an iquity hunters in Greece, and it is proposed to lend it to Virchow for examination.

A New Medical School.—The Trustees of Tuft's College, in Massachusetts, have decided to establish a medical school in Boston. The school will admit students of both sexes.

The Mortality of New York State.—According to the bulletin of the State Board of Health, there was an average daily mortality during July of 398, against 291 in June, which was the lowest rate for the year; in July, 1892, however, the average was 437. From zymotic diseases, with the exception of diarrhœa, there were fewer deaths in July than in June. The deaths from diarrhœal diseases increased from 478 in June to 3,200 in July, twenty six per cent. of the total mortality for the month. The latter figure, however, was less than for July last year, and less than the average, which is about twenty-eight per cent. The infant mortality is correspondingly

diminished, 50.5 per cent. of the deaths having occurred under the age of five years, the average for July being 51.5. In the cities of New York, Brooklyn, and Buffalo forty per cent. of the deaths were from diarrhœa; in the rural parts of the State only 7.3 per cent. of the deaths were from this cause. Scarlet fever and measles continue to decrease in all parts of the State. Diphtheria is slightly more prevalent than is usual for this season. There were sixteen deaths from small-pox. There was a large increase over June in deaths reported from diseases of the digestive and nervous systems. The following percentages represent an annual death-rate per 1,000 inhabitants in certain cities of the State for July: New York City, 29.87; Brooklyn, 29.57; Long Island City, 48; Yonkers, 30.35; Mount Vernon, 36.28; Albany, 21.55; Poughkeepsie, 23.78; Newburg, 29.89.

Dr. O. H. Bartine, of Princeton, died recently aged seventy-eight years. Dr. Bartine was born in Mercer County, N. J., and was at one time Mayor of Princeton. He had resided in Princeton for forty-six years.

Dr. N. A. Garrison, of Stony Point, Rockland County, N. Y., died suddenly of heart disease on August 26th. He was fifty-six years of age.

A Distinguished Americanist.—Dr. Daniel G. Brinton, the Philadelphia archæologist, is supposed to know more about Indian antiquities and languages than anybody else in America. He can converse with fluency in Choctaw, Muskogee, Natchez, Maya, Quiche, Arawack, and other soft-sounding Indian dialects; but is at the disadvantage of being rarely able to find a person accomplished enough to talk with him in those tongues. Dr. Brinton was the first to classify the tribes of American Indians by their languages, and he has read all that is discoverable of their literature.—*The Tribune.*

The Red Cross and the Projected Samaritan Union.—Dr. Joseph Kühn, of Vienna, in a recent pamphlet, controverts the arguments of Professor Billroth in favor of the proposed Samaritan Union. A few of Dr. Kühn's points are as follows: As the Red Cross Society, to which is intrusted the noblest tasks of humanity both in war and peace, is one of vital importance, it will be eminently proper to examine the proposed movement carefully, and ascertain if in reality its advantages would be as great as its projectors would have it believed. The Union proposes to take care of the physical well-being of the people, which, according to law, is the duty of the communities under the direction of the government, and for this work the Union desires a yearly appropriation from the state. Although this is a fair proposition, it is obviously the sounder principle to educate the communities in sanitary measures and help the poorer communities to build hospitals, etc., whenever and wherever necessary, directly from the treasury of the state rather than indirectly through an association. If the plans of the Samaritan Union were carried out, the communities would become more and more dependent on the Union, therefore would be crippled in their independent prophylactic measures, and in a formidable epidemic would be helpless. In the event of war the dependent communities would be left without resource, as it is expressly stipulated that then the entire *personnel* of the Union must be turned over to the Red Cross. This would paralyze the public sanitary service and expose state and community to great danger. Even though the Samaritan Union were actually to render valuable assistance in times of great calamity, it would still be contrary to sound business policy, for in a long time of peace the people would lose sight of the activities of the Red Cross, and the latter would thus be hampered in the collection of funds to carry out the provisions of its great work, viz., the care of the sick in war. As there is no better way of preparing the Red Cross for war than in the perfecting of its aid service in time of peace, and as the important provisions of the two services are the same, therefore, to be harmonious, they must be under one organization. The Samaritan Union, in urging the voluntary aid service, overlooks the important facts that the Red Cross has been authorized by law to provide such service, and that there are already many allied aid societies in existence. The centralization plan of the Samaritan Union was tried very thoroughly in Germany a few years ago by Dr. Fredrich von Esmarch, who established a union, erecting schools where first aid to the injured could be taught practically. Though the ideas there promulgated were excellent, the plan met with scant success; as the other great humane societies were already established, and received all who desired to join aid societies. In this movement Dr. von Esmarch did not in any way seek to destroy the activity of the Red Cross in time of peace, but, on the contrary, did everything in his power to encourage it, recognizing the vital necessity of all aid societies being under one management. If the Samaritan Union was established as proposed, supported and sustained by the state, Dr. Kühn thinks it would tend to disorganize and ruin the Red Cross Association.

The William F. Jenks Memorial Prize.—The third triennial prize, of five hundred dollars, under the deed of trust of Mrs. William F. Jenks, will be awarded to the author of the best essay on "Infant Mortality during Labor, and its Prevention." The conditions annexed by the founder of this prize are, that the "prize or award must always be for some subject connected with obstetrics, or the diseases of women, or the diseases of children;" and that "the trustees, under this deed for the time being, can, in their discretion, publish the successful essay, or any paper written upon any subject for which they may offer a reward, provided the income in their hands may, in their judgment, be sufficient for that purpose, and the essay or paper be considered by them worthy of publication. If published, the distribution of said essay shall be entirely under the control of said trustees. In case they do not publish the said essay or paper, it shall be the property of the College of Physicians of Philadelphia." The prize is open for competition to the whole world, but the essay must be the production of a single person. The essay, which must be written in the English language, or if in a foreign language, accompanied by an English translation, should be sent to the College of Physicians of Philadelphia, Pa., U. S. A., before January 1, 1895, addressed to Horace Y. Evans, M.D., Chairman of the William F. Jenks Prize Committee. Each essay must be typewritten, distinguished by a motto and accompanied by a sealed envelope bearing the same motto and containing the name and address of the writer. No envelope will be opened except that which accompanies the successful essay.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Sixty-first Annual Meeting, held at Newcastle-on-Tyne, August 1, 2, 3, 4, and 5, 1893.

(Continued from page 284.)

(Special Report to the MEDICAL RECORD.)

SECTION OF SURGERY.

FIRST DAY, WEDNESDAY, AUGUST 2D.

IT having been decided that in order to save time presidents of sections should not deliver addresses, Dr. Arnison merely prefaced the business of the Section with a few remarks. He much regretted that Dr. Halsted, of the Johns Hopkins University, in Baltimore, who was to have opened the discussion on the "Radical Cure of Hernia," was prevented by illness in his family from being present. Mr. Mitchell Banks, who was to have taken part in the discussion, was also prevented by illness from doing so.

A resolution of regret and sympathy was passed by the Section unanimously, and ordered to be forwarded to Dr. Halsted and Mr. Banks.

Radical Cure of Hernia.—MR. RUSHTON PARKER, of Liverpool, then opened the discussion. He had practised the operation during fourteen years on 251 cases, omitting 25 that died from strangulation. Of 61 strangulated 30 were inguinal, 21 femoral, and 10 umbilical and ventral. He included here no deaths, as they resulted from strangulation and not from the operation. In 190 unstrangulated cases 137 were inguinal in 107 persons, with 5 deaths, or 3.6 per cent.; 25 were femoral in 20 persons, with 1 death, or 4 per cent.; 28 were umbilical or ventral in 24 persons, with 2 deaths, or 7 per cent. Of the 137 inguinal cases 22 were infants and children under twelve years (one strangulated at the age of three weeks remaining up to now, after nine years, a radical cure); and 21 unstrangulated, with 1 death, or 4.7 per cent. He thought that all methods were liable to fail sometimes. He could not give a trustworthy estimate of the proportion of failures among his cases, but he thought that they were few. He had practised ligature of the sac in rather less than half the cases, and suture in rather more than half. He stripped the sac from the vessels and duct in order to ligature and suture, leaving the lower part of it *in situ*. Since he had become acquainted with Macewen's operation he had practised it exclusively. In femoral hernia he made no attempt to unite the edges of the ring.

Failures were owing sometimes to flabbiness of the patient's tissues, or too tight distention of the abdomen, or to recumbency after operation not being long enough enforced. This last cause was most common in hospital patients, who were not so easily controlled or so amenable to reason as private patients, among whom complete success was the rule. He had found that carbolized or chromicized catgut was too quickly absorbed in many cases, and he preferred the sulphurized gut or silk. He had had one fatality in a child in whom the whole of the small intestine was in the sac. He thought that this death would not have happened had he had his present experience at the time. The child was ten years of age, and treated as an out patient. Eight out of twelve cases were treated by ligature, with 1 death and only 2 recurrences.

Macewen's method was sometimes difficult of execution. He had used it in more than one hundred cases. Some cases after operation suppurated, but he thought that this was due to modifications introduced by himself which he had since abandoned. In a few cases in infants recurrence had followed. The younger the patient the better the result. In umbilical hernia he had satisfactory results from ligature of the peritoneal lining of the sac, but this sometimes failed. He had had better results after dealing with the sac by what he called the "double-breasted-coat method." This consisted in forming either two lateral or upper and lower flaps, and uniting the free edge, each one to the base of the other, by two rows of sutures, but he had had recurrences in some of the most severe cases where radical cure was most called for. Of 40 operations for umbilical and ventral herniæ 13 were on strangulated cases, with 3 deaths, and 27 on unstrangulated cases, with 2 deaths.

In conclusion he would say that a radical cure in young children or infants was almost certain of attainment, and in adults in a majority of cases. Umbilical hernia in adults was not so curable as femoral and inguinal hernia.

MR. WARD COUSINS, of Portsmouth, said that in his opinion the great question was, "What is the best operation?" All were more or less successful. The best were those of Mitchell Banks (who was a pioneer in this line), Macewen, and Halsted. Even in unsuccessful cases the patients were benefited, as they were enabled to wear trusses with safety and comfort. The same operation was not applicable to all cases. Each must be treated on its merits. It was useless to say that the sac should always be removed or the pillars always stitched. He had treated one hundred and twenty cases in children from seven years old to twelve months, and also many adults. In eighty per cent. a thorough cure had followed one operation, in three-tenths of the remainder he had repeated the operation. Parents were now very anxious to have the operation done, as hernia was a disqualification for the public services, and in the neighborhood of Portsmouth many children were intended for the army or navy.

The operation as he performed it was very simple. He did not open the sac when it was empty. After exposing the sac and stopping all bleeding he peeled the sac from its surroundings close up to the ring, and ligatured it as high as possible, placing a second ligature, less tightly drawn, half an inch lower down. He then tucked up the sac into the inguinal canal. He had had no deaths from the operation, but two from influenza. The management of the bandage after operation was most important. He entrusted his cases to skilled nurses, who were careful to support the part with the hand during washing or whenever the bandage was temporarily removed. He usually ordered a light truss after operation, as crying and straining were likely to cause protrusion. He believed that there was a great future before the operation, which was simple and safe in early life.

MR DAMER HARRISON said there were three principal ways of operating. 1. Simple ligature of the sac without suture of pillars of the ring. 2. Mitchell Banks's operation dealing with the pillars. 3. Macewen's. The first method was followed by no more recurrences than the others. He thought that the pillars might safely be left alone. He had had no recurrences since he had done Macewen's operation. It was a mistake to suppose that suppuration and the formation of scar tissue produced the best results. The contrary was the case. He used no drainage except in very large herniæ and had given up even the horse-hair drain during the first twenty-four hours. Cicatricial tissue was not useful as a protection. He had had trouble with Banks's operation from the stitches setting up inflammation and suppuration.

DR. CRAWFORD RENTON, of Glasgow, thought that early operation was best, as the tissues had not yet become thinned and altered, but in children many cases were cured by the use of proper trusses. He would operate on all irreducible hernia in adults, whether strangulated or not. He preferred Buchanan's operation in children and Macewen's and Banks's in adults. For old cases it was difficult to detach the sac, and it should be cut off.

MR. PYE SMITH said that inguinal hernia in infants had, like phimosis, a tendency to spontaneous cure when the gut was kept out of the sac. He quoted statistics to show that many cases must undergo natural cure early in

life. He had had one fatal case of operation for radical cure.

Mr. Stanmore Bishop said there were two important points for consideration. First, as to the advisability of operation; and second, as to the choice of operation. There was great difference of opinion on the first point. Enough attention was not paid to the causes of hernia. The causes of strangulated hernia were different from those of reducible hernia. The causes of the latter were preventible, and were difficulties of defecation—such as piles, worms, etc.—difficulty of urination, and also the occupation of the patient.

We ought to be able to combine in one operation the best points of all. He took a truss which consisted of a pad and a spring as typical of the result aimed at. What was the best pad? and what the best means of repairing the broken spring of the abdominal wall? Macewen was the first to propose the spring and pad. He had modified Macewen's method of forming the pad, and explained his modifications. He did not separate the sac beyond the ring, as its nutrition was otherwise apt to be interfered with.

Mr. R. C. Chicken offered a few "heretical opinions." He disagreed with much that Mr. Pye Smith had said. He had never had a failure in a child. He thought that the most favorable cases were those where no truss had ever been worn. Most herniæ, in his opinion, were really congenital in origin, the sac having been down since birth. The sac in these cases was composed of interlacing fibrous bands, and was strong and distinct, and often thick and quite different from the sac of a truly acquired hernia, which was thin and often imperceptible. In the latter the sac cannot be manipulated. As to suture of fascia, in this region the fasciæ were very movable on one another, and unless the aponeuroses were laid bare and sutured union would only be temporary. It was very difficult, and often impossible, to distinguish between the peritoneum and the transversalis fascia, and this Macewen acknowledged. A very light truss produced no absorption when union had been primary. He preferred cotton ligatures, soaked for twenty-four hours in pure carbolic acid and afterward boiled for one hour in a five per cent. solution, to all others. He had had no suppuration when using these; with various other ligatures he had had trouble.

Mr. Butlin though it was still doubtful which cases were the best for operation. All cases should be operated on until it was clearly shown which were the best. Each surgeon should do the operation with which he was most familiar. He thought removal of the sac was essential.

Mr. Jessop said that the question of strangulation had not been considered enough. Should we in all cases of strangulation not only relieve this condition, but also attempt radical cure? He thought we should.

Mr. Rickman Godlee said the simpler the operation the better. He sutured the pillars and had had very good results.

Mr. Rutherford Morrison spoke of Halsted's practice, which he had watched in Baltimore. He thought his operation the best. The presence of the spermatic cord was agreed to be the cause of recurrence, and Halsted's operation removed the cord from the inguinal canal and rendered its obliteration possible. Dr. Halsted had lately much simplified the procedure.

Mr. Ward Cousins thought that the large scar would be a drawback and prevent patients entering the public service.

Mr. Rushton Parker, in reply, said that it was not necessary to strip all the sac from the scrotum; it did no harm, but it must be stripped up in its upper part to allow of ligature. He had followed Professor Lister's method of dressing the wound, and now used cyanide gauze, etc. He did not use or approve of included wire sutures. The supposed advantage of the results of suppuration was "all moonshine." The quicker the union the better. As to the use of trusses, some patients did not mind them, but others strongly objected to them, and one elderly patient had said to him: "I don't mind dying, but I'll be d——d if I'll wear that infernal truss any longer." This remark expressed the feelings of many patients.

Mr. W. Mitchell Banks said that since he first commenced, about the year 1880, attempting the radical cure of hernia, he had only performed the operation 168 times, 117 times on non-strangulated and 51 times on strangulated herniæ. He had always publicly expressed a strong opinion that no operation (except for very special reasons) should be performed on an adult who can keep up his rupture securely and comfortably with a truss, for a light and well-fitting truss is hardly any inconvenience to a patient, and is very far from being the bugbear which the advocates of the indiscriminate use of the radical cure would make it out to be. As regards infants, he believed they may all be cured by well-fitting trusses. Of the 117 non-strangulated cases not one was operated upon who could wear a well fitting truss, except in special cases, such as where a man was going abroad to a place where no medical help was to be had, or where he had some extremely violent labor to perform which might break down any truss, or where it was necessary for a public appointment that he should be entirely free from rupture.

The operation was the same in all the cases. In femoral herniæ it consisted simply in dissecting out and removing the sac as high up as possible. In inguinal herniæ, in addition to this, the pillars of the external ring were pulled together by two or three silver wire sutures, which were left in position after their ends had been cut very short. He does not put these in with any object of securing a permanent closure of the external ring, but simply to make sure that the hernia shall not descend for a considerable period, so that the inguinal canal (if it be in fairly normal case) may have a chance of contracting. Unless some extensive "rawing" of the walls of the canal is done, he believed all stitching of it to be of just as much use in procuring permanent union as stitching the edges of a cleft palate would be without freely refreshing them. The speaker's reason for adhering to the operation which he had hitherto used was that it is the simplest of any that has yet been devised. Ruptured people are in every place and in every station of life, and the operation for their cure should be such that not merely experts or specialists could do it, but that any surgeon to a cottage hospital should be able to perform it.

Statistics of Mortality.—Among the 101 moderate-sized non-strangulated herniæ 2 deaths are recorded. One was distinctly due to the operation. It was a case where there was a "land slip" of the cæcum down into the scrotum, which is a very dangerous condition. The other was doubtful, as the wound was all but healed.

Of the 16 very large and enormous herniæ 4 cases proved fatal. Septicæmia killed 2 patients, and unsuspected abscess, bursting into the peritoneal cavity after the patient was walking about and deemed sound, proved fatal in another, while in the fourth the operation could not be completed.

Of the 26 cases of strangulated inguinal herniæ, 1, an old man, aged seventy-seven, died from septicæmia and bronchitis. Of the 24 cases of strangulated femoral herniæ 2 died; one never recovered from the collapsed state in which she arrived at the Infirmary, and the other was moribund when admitted. The mortality of the radical cure in moderate-sized herniæ was, therefore, two per cent., and of the strangulated herniæ six per cent.

Statistics of Permanence of Cure.—Of the whole 168 cases it has been possible to trace for very considerable periods 113. Of these, 79 remain quite sound, 19 are partial successes, and 15 are complete failures. The majority of the failures occurred either in very degraded people, who took no care of themselves, or in persons who had very severe work to perform and began it too soon.

Surgical Treatment of Ulcer of the Stomach.—Mr. Haslam then read a paper on some points in the surgical treatment of simple ulcer of the stomach.

Perforation of the coats of the viscus occurred in some cases, but the position of the ulcer much affected the gravity of the result. When on the posterior surface adhesions generally formed, and general peritonitis was by them prevented. When perforation happened, and adhesion with a neighboring hollow organ existed, a fistula would result.

He described a case in which perforation occurred and he had operated three hours after the onset of symptoms. Death occurred forty-five hours afterward. The patient had had no clear symptoms of ulcer before perforation. The symptoms of perforation were sudden vomiting (but this was not always present), pain almost invariably, sometimes increased by pressure and sometimes relieved by firm pressure. In operating the incision should be to the left of the middle line to avoid the falciform ligament. The part of the stomach first met with was the lower edge of the anterior surface. The ulcer would often be found to be apparently on the upper surface. The advisability of excising ulcers before perforation occurred was considered. He used Lembert's sutures, and thought that pelvic drainage was advisable, as it made easy the flushing of the peritoneum.

Aneurism of the Subclavian.—Mr. Coppinger, of Dublin, showed his case of aneurism of the second and third parts of the right subclavian artery cured by ligature of the innominate. The case has been described in the medical journals at the time of operation and since. The aneurism is now (seven months after operation) represented by a hard lump about the size of a large walnut. Mr. Coppinger said, that although no pulse could be felt at the right wrist, the arm and forearm were normal in temperature, color, and nutrition. Some members thought that a very faint pulsation was perceptible in the radial artery.

Second Day, Thursday, August 3d.

Surgical Treatment of Cerebral Tumors.—Mr. Victor Horsley opened the discussion on the surgical treatment of tumors of the brain. He would say there were three chief points to be considered. First, the treatment of the case previous to contemplated surgical interference; second, by the objects to which that interference should be directed, and lastly, the technique of the operation. He premised that a case of cerebral tumor meant one in which there were progressive localized symptoms. It was notorious that before the nature of the case was known the symptoms might be few and their localization undiscovered. He wished to elicit a distinct expression of opinion as to how long it was justifiable to continue medical treatment before resorting to surgery. At present cases were not submitted to the surgeon, as a rule, till they were beyond hope of cure by operation. He would venture to suggest that treatment by drugs should not be prolonged beyond six weeks. It was admitted that no kind of cerebral tumor was curable by drugs, except it were perhaps a gumma or a tuberculous nodule. In the latter case treatment by arsenic, cod-liver oil, etc., might be continued longer than that by iodide of potassium in a syphilitic case. Say for four months as against two. He protested against operation being used only as a last resort instead of as a primary method of treatment. He thought that the only possible way of curing a cerebral gumma was by removal. Optic neuritis was, of all the results of cerebral tumor, one of the most melancholy, and early operation alone was likely to check its progress. He projected micro-photographs of certain endo-cranial tumors on the screen by means of the lantern, and remarked on the tendency of some to degenerate. He was convinced that the pericranium had no osteogenetic power, and that therefore it was of no importance whether it were separated from the bone or not. As to reimplantation of the bone removed in operating, he preferred the American plan of implantation of the whole piece, or pieces, to that originally used by Macewen, of dividing it into small fragments.

Mr. Horsley described a case of Jacksonian epilepsy, and extensive and progressive motor palsy. A tumor of the motor area was diagnosed, and on operating he found it to be about two by two and one-half inches. It shelled easily out, leaving a corresponding cavity. The patient recovered from the operation; but five hours afterward chloroform vomiting set in and patient died. Necropsy proved that hemorrhage into the cavity had occurred, and the thin wall of brain matter dividing it from the lateral ventricle had yielded and the blood had filled the ventricle and passed on to the fourth ventricle. He would now in a similar case tampon the cavity. Opening the lateral ventricle was, of course, not in itself fatal.

Shock was a common cause of death in cerebral operations, but it might be largely diminished by dividing the operation into two stages—first, trephining and opening the dura mater; and removing the tumor at a second operation a few days later. Treatment by drugs alone was dangerous, and of little use. Surgical interference held out the only hope of cure in most cases of intracranial tumor. Mr. Horsley demonstrated his electric saw, which he preferred to the trephine, the pressure of which on the skull was sometimes dangerous.

Mr. Macewen referred to two cases of cerebellar tumor under his care (one of which was cured), of absolute palsy of the lower extremities and extensive loss of power in the upper limbs, and incontinence of urine. In another case the palsy was little improved, but severe and constant headache, which had been the most distressing symptom, was quite cured. This result alone was worth operating for. He had several times operated in two stages, not to prevent shock but to avoid subdural bleeding, adhesion occurring, and thus removing the risk of blood being extravasated and travelling, as it might do, down to the base of the brain. He was glad to hear what Mr. Horsley had said about the absence of osteogenetic power in the pericranium. He would himself extend this statement to all periosteum. After trephining in children he would reimplant the bone *en masse*, but in adults there was a risk of partial necrosis. He therefore preferred to divide the bone, but not into such small fragments as he did formerly. In some instances he had removed a rectangular piece of bone, cutting along three sides with the chisel and dividing the base by a row of drill-holes. He thought that the high-speed saw and the circular saw were not safe except in very experienced hands. The vibration made delicate application difficult, and a vessel might be wounded inside the skull before the bone was removed, and fatal bleeding follow. He agreed with Mr. Horsley that cases as a rule were kept too long under observation before operation was decided on.

Mr. Damer Harrison said he was there to ask questions, and seek information. He had only operated on one case of tumor, which died, he believed, because operation was too long delayed. Hemorrhage was often difficult to treat.

Mr. Rushton Parker approved of the position taken by Mr. Horsley. He narrated a case of his own which was related at the 1889 meeting. Here the dura mater was adherent and umbilicated. The patient was doing well when Mr. Parker, twenty-four hours after operation, inserted a drain, with the result that sinuses formed, and the operation had to be repeated to remove them. After much trouble the man recovered. He deprecated such meddling.

Dr. Lanz, of Berne, said that Rocher had several times established permanent drainage of the lateral ventricle as a palliative measure, by means of a trocar and cannula and glass-tube, with good effect.

Dr. Nicholson mentioned a case on which he had operated. There was bulging of one parietal bone. On opening the skull the bleeding was so alarming that, fearing immediate death, he applied pressure and closed the wound. The man died six months after, with a sarcomatous mass as big as a hat outside the skull.

Dr. Cathcart thought that the classification of tu-

mors was too rigid, and that there was no hard-and-fast line between sarcomata and fibromata.

Dr. Newman, of Glasgow, said that sarcomata were sometimes encapsuled at first, and growth was very slow until the capsule was divided or gave way.

Mr. Victor Horsley, in reply, said that he had suggested six weeks as a limit to the medical treatment of tumors in those supposed to be malignant only. He did not attach much importance to subdural bleeding, as the brain expanded and the vascular pressure improved after opening, and the subdural space was obliterated. There was no such space in life normally. The vessels of the meninges were important, and should be ligatured all round the site of incision before it was made. In cases of bleeding under the dura mater he would enlarge the opening fearlessly, and find and tie the vessel or vessels. He had not tamponed wounds hitherto, because he held that immediate union was to be hoped for. He would reserve tampons for cases where a large cavity was left in the corona radiata, using successive strips of gauze. He would undertake it with hesitation. No one should operate who was not familiar with the appearance of normal living brain, and this familiarity was only obtainable by experiments on living animals. He doubted the correctness of Macewen's views as to the osteogenetic power of the periosteum, except in the flat skull-bones. He thought that the nutrition of the fragments of bone reimplanted was damaged by the force used to cut them up, and for that reason would continue to use the bone *en masse*.

Splints for Fractures of the Lower Extremity.—Mr. W. Arbuthnot Lane read a paper on the fallacy of the vertical foot piece. He said that he would attempt to prove that the practice of putting up fractures of the lower extremity in splints, with foot pieces so placed in a vertical transverse plane that the inner margin of the foot was vertical, was fallacious and unscientific. The normal position of rest of the foot in the supine position was one of eversion about forty-five degrees. This was due to the fact that the centre of gravity of the limit lay outside a line from the acetabulum to the heel. He described various experiments on the dead body, showing the effect of the usual foot-piece in preventing union in intracapsular fractures of the neck of the femur, and in producing mal-union in other parts of the limb. That results were not worse was due to the foot slipping away from the splint, and to the use of splints without foot pieces. The more careful the surgeon, the worse the result with the vertical foot-piece.

Mr. Damer Harrisson agreed with Mr. Lane. In Liverpool, owing to the late Mr. Thomas's influence, the foot-piece was not so much used as elsewhere. The great discomfort felt by persons kept on their backs with a splint might be due to the inversion caused by the foot-piece.

Mr. Pye Smith agreed. He thought that the good results of treatment with Hodgen's splint were due to its having no foot piece.

The President thought that results hitherto had not been so bad. He was ready to take a hint, however, from Mr. Lane's paper.

Dr. Peters, of Toronto, said he would like to know how Mr. Lane put up his fractures. Experiments on the dead body were not altogether trustworthy. The conditions were not the same as in life. Some splints having vertical foot-pieces supported the leg and thigh, and so prevented rotation inward of the lower fragment. In Canada the Scotch sheet was much used. Certainly some deformity often resulted, but eversion of the foot, and not inversion, was the rule.

Dr Newman, of Glasgow, said that treatment of fractured femur was a complicated question. He advocated simple weight extension, especially in fractures about the middle. Frequent inspection of the site of fracture was then easy.

Mr. Lane, in reply, complained that our surgery did not rest enough on principle. We were too much inclined to follow individuals like disciples. He could not agree with the President. He thought the results of our treatment of fractures miserable. The particular splint employed was not important so long as true principles were followed.

Angular Gouge for Operations on the Skull.—Mr. Lane then read a paper on "The Applicability of the Parting Tool or Angular Gouge to the Surgery of the Skull." He had for many years discarded the use of the trephine, as he considered it a clumsy and unsuitable instrument. Instead of it he had used gouges, and preferably those ground on their concavity, and with them he found that he could remove large pieces of bone with comparative rapidity. It occurred to him that an instrument with its sharp free margin presenting the form of two sides of an equilateral triangle, similar to what is used in carpentry, and is called a parting tool, if ground on its inner surface, would remove bone much more rapidly than the concave gouge.

He had had made instruments of suitable temper, and found that the results obtained more than came up to his expectations, since he was able to remove areas of bone of any form without injury to the dura mater and with great rapidity. He found it convenient to use two different gouges so ground that one was more suited to the thicker dense skull of the adult, and the other to the less resistant skull of the child. At first sight one would imagine that there would be some risk in injuring the dura mater with the sharp angle of the instrument, but with the most ordinary care there does not appear to be any risk of doing so. Certainly, he believed, that there was infinitely less risk to the dura mater in using the angular gouge than the trephine, and the mechanical advantages of the former over the latter only required a trial to demonstrate them.

Mr. Damer Harrisson preferred the chisel to the trephine, especially when there were symptoms of brain pressure. The operation was more rapidly done, but the concussion of the blows of the mallet was a drawback. He thought Horsley's electric linear cutting saw best. Several other speakers followed to the same effect.

Mr. Lane, replying, said that the mechanics of the gouge bevelled on the inner concave surface were very different to those of the carpenter's gouge. The parting tool need not be held in a position near the vertical, and almost all the force of the blows was spent on driving it in a plane nearly parallel to the surface.

Hydrocephalus.—Dr. J. Hern read a paper on the effect of repeated tappings on hydrocephalus. He showed a boy, aged six years, whom he had first tapped at the age of two. There was then extreme strabismus, and no perception of light in the left eye. Tapping was repeated at intervals of three or four months, two or three ounces being removed with the aspirator. The head ceased to enlarge, the crying ceased, and the child began to take interest in things. The vision of the left eye was now about one-fourth of normal, and the squint had diminished. The boy was now bright and intelligent. Symptoms began in this case, after convulsions, at ten weeks. He had treated six cases in this way, with one death. The fatal case was tapped eighteen times. The necropsy showed a large cerebellar tumor pressing on the pons.

He preferred to aspirate through the anterior fontanelle, making the skin puncture a little to one side of the opening, and passing the needle obliquely under the skin into the fontanelle. The head should be kept low during the operation, and the fluid be drawn off slowly. The other four cases had not long been under treatment, but he was hopeful as to the results.

Mr. W. A. Lane could only congratulate Dr. Hern on the case shown. He had tried tapping, but the results had been miserably unsatisfactory. He had aspirated and also left a minute cannula in the skull to allow of permanent drainage. Improvement had only been temporary.

Mr. Rickman Goodlee had had similar experience. Some cases improved without treatment, and he thought

that the one before them must be of that nature. A great many surgeons had told him that they had tried tapping but had given up the practice.

Dr. Newman said that the skull in hydrocephalus was more resonant on percussion than when normal. In this case he found the resonance was normal. Was this so at first? The pathology of the disease led one to expect little permanent benefit from tapping. As long as there was a physical obstruction to venous return from the choroid plexus tapping could only be palliative, and if too much fluid were withdrawn at a time the engorgement of the plexus would be increased. In ascites from cirrhosis of the liver, tapping was similarly only a palliative.

Dr. Hern said, in reply, that he had not been able to make sure that the percussion note permanently improved. Improvement occurred immediately after operation. He had known cases of cirrhosis of the liver get well after tapping, and he did not see why hydrocephalus might not. At any rate, for the sake of the mother, the attempt was worth making.

Pylorectomy.—Mr. Rutherford Morison showed specimens from cases of pylorectomy, etc. One was from an old man who died suddenly five days after operation. Another, from a case of cancer in which gastroenterostomy was done, showed a silk suture still attached four months afterward when death occurred. The third case showed the importance of making a very large communication between the parts at the time of operation. In the fourth case the stomach was much dilated, and there was extensive ulceration about the pylorus. The patient regurgitated pancreatic and gastric fluid and died. Mr. Morison also showed a new apparatus that he had devised for treating cases of gangrenous bowel or artificial anus. It consisted of a combination of Dupuytren's spur-divider and Paul's tube, made in metal instead of glass. He had only used it in experiments on the dead subject. He illustrated his paper by diagrams.

Third Day, Friday, August 4th.

Treatment of Intestinal Obstruction.—Dr. Frederick Page read a paper on this subject. Many conditions caused the symptoms of acute obstruction, and all were dangerous. Our treatment should depend on the cause.

In hernia he advocated operation as early as possible, and the same treatment was advisable when the strangulation was internal; but in that case it was often difficult to tell whether there was strangulation or not. In a great majority of cases there was mechanical obstruction or perforation. A small proportion would recover without operation. The mortality after abdominal section was high, and so it used to be in hernia, because the operation was too long delayed. The risk of opening the belly was small. He did not propose in this paper to deal with the various conditions and kinds of operation advisable. He would urge the importance of not waiting. Other means could very seldom be of use, and when unsuccessful they were harmful. Chronic obstruction was generally due to affection of the large intestine, and early operation was less imperative, but even here the anterior incision was best. In subacute cases the best criterion was the effect the disease was producing on the patient.

Taxis in Hernia.—Mr. Jonathan Hutchinson agreed with Dr. Page's concluding remarks, but dissented from much that he had said. He stood there as an apologist for careful and patient taxis. He regretted that Dr. Page had given no statistics. He assumed too much that the success of hernia operations had increased, and that from not using taxis. Mr. Hutchinson said that he found that modern surgeons taught students that the taxis was not to be tried in strangulated hernia. The rule was to operate without trying taxis. He emphatically denied that the modern practice had improved the statistics. At the London Hospital, which was the hospital with the largest hernia practice in London, or perhaps anywhere, in 1861, thirty-three per cent. of operations on strangulated hernia were fatal. At St. George's Hospital, at the same time, thirty per cent. were fatal. At the London Hospital now fifty per cent. of these operations were fatal! Although statistics were proverbially misleading, he could find no fallacy here. He would not say that this increase of fatality was general, but he knew of no hospital where the fatality was much diminished, and certainly modern operative treatment could not anywhere show so low a fatality-rate as thirty per cent. In his opinion it was wrong to suppose that operation itself entailed no extra risk. It added considerably to the risk. He spoke from an experience of twenty-six years at the London Hospital. In all cases of strangulated hernia that came under his care he tried taxis. In one year he operated on two cases at the hospital, in another only on one, and in another year on none. He could not, moreover, remember a single death after successful taxis in his own practice, while the fatality of operated cases was thirty per cent.; and this was due to no want of skill in his colleagues, one of whom at least was as skilled in abdominal surgery as anyone living. Opening the sac of a hernia did entail some risk. It was not right to compare operations on healthy peritoneum with those on a strangulated sac. Comparison of operations which differed in kind and conditions was fallacious. The mortality from cutting operations on strangulated hernia was still high, and had not been diminished by modern surgery. Cases which were operated on without opening the sac were much more favorable, this operation being a kind of partial taxis. Let him not be understood to plead for delay of treatment. Treatment should be actively undertaken as soon as possible. The position of the patient was important. Ice was of great value. Manual dexterity, however, was the chief requisite. This dexterity was in danger of being lost by the rising generation of practitioners, for the modern school forbade forcible taxis and frightened students so that they dare not try it. Taxis, to be of use, must be forcible, but the force must be rightly applied. He had often used taxis till his hands were tired and he had to give place to an assistant. He gave details of a case where perfunctory taxis was tried in vain, and operation showed that forcible and well-directed pressure would have cured the patient. The surgeon who operates cannot avoid the risk due to opening the sac.

Non-Operative Treatment of Intestinal Obstruction.—As regards internal intestinal obstruction, he objected to too much generalization. We must classify. He was a most diligent student of the periodicals and the literature of the subject generally, and he took every opportunity of inquiring of other surgeons. The conclusion he had come to was that abdominal taxis was far more successful in the long run than laparotomy. Judicious taxis did no harm whatever, and would cure a large proportion of cases. It was not possible to define acute obstruction, and he objected to the use of the phrase. In many acute cases there was nothing that operation would cure. There were a few cases that could only be cured by laparotomy, but there were at present no means of distinguishing these. He could mention at least a dozen cases presenting the symptoms of so called "acute intestinal obstruction" which had been cured by taxis. The taxis he employed consisted in inversion of the patient, forcible shaking, and pushing of the intestines from side to side, and the administration of large enemata while the patient was inverted. Chloroform must, of course, be given first. Sometimes the immediate result would be nil, but an hour or so afterward a motion would be passed and all go on well. He gave details of several cases illustrating this. We must not assume that in all cases the gut was tightly held by a band and strangulated. In many cases operation showed that a very slight force would free the intestine, and taxis would probably have succeeded at the London Hospital. He knew of no case of laparotomy from acute obstruction, while he was surgeon, that had recovered, excepting cases of intussusception, which were a class apart. He knew of only one successful case there since he became consulting surgeon. As in hernia, he believed that the operation increased the risk

to the patient. It was, for instance, absolutely impossible to diagnose gall-stones as a cause of obstruction. The history of such cases was most delusive. He knew of four cases of gall-stones that had been diagnosed by the best surgeons as due to band, and operated on. Only one case was cured. The results he had obtained in such cases, the nature of which had been afterward proved by the passage of stones, were uniformly good.

He had never seen a necropsy that made him regret that the belly had not been opened, and yet he examined every case that he could after death. He most strongly urged that abdominal taxis under an anæsthetic ought to be the first resort. It should be done early and faithfully, and if it failed it did no damage to the prospects of an operation. When there was peritonitis from the beginning he would not use taxis. What was to be done when the taxis failed? Each case must be discussed on its merit. No general rule could be laid down. He thought that laparotomy theoretically was good surgery, but he feared that it was bad practice.

Dr. Halliburton Hume said that all surgeons must agree with Mr. Hutchinson as to the unsatisfactory results of operations at present. He thought, however, that the use of unsuccessful taxis much damaged the prospects of operation. He held that the special state of the peritoneum in strangulated hernia, asserted by Mr. Hutchinson, was much aggravated by taxis. He had the same objection to abdominal taxis. Improvement must be sought by attempting the differential diagnosis between inflammatory conditions and mechanical causes. The previous history of the case was most important.

Mr. Ward Cousins believed that abdominal taxis was the very best treatment to adopt, as a rule. He had saved three cases by it. The symptoms of the different conditions which caused obstruction ran so much into each other that exact diagnosis was impossible.

Mr. Walter Rivington said that Mr. Hutchinson has not stated the real reason of failure of laparotomy. This was the delay that occurred before the surgeon was called in. His experience at the London Hospital was that physicians kept acute cases, as a rule, at least three or four days, and he had known three weeks to elapse before the surgeon was called in. A fair comparison would be between cases of twenty-four hours' duration only. Abdominal taxis and laparotomy were not opposed to one another. They should be both used if necessary.

Dr. Newman was glad to say that all cases of acute intestinal obstruction were now admitted at once into the surgical wards at the Glasgow Royal Infirmary. During ten years as pathologist he had seen many cases that might have been saved by operation, and never one in which death was directly due to operation. In hospital cases often no history was obtainable, and when obtainable it was not trustworthy.

Dr. Tyson, Mr. Rutherford Morison, Mr. Haslam, and Dr. Wilkinson also spoke, after which Dr. Page briefly replied. The Section then adjourned.

OBSTETRIC SECTION.

Second Day, Thursday, August 3, 1893.

Puerperal Septicæmia.—Dr. Robert Barnes, of London, in opening a discussion on this subject, said that the questions that presented themselves were, "What is puerperal fever?" and "Is there a true endogenetic septicæmia?" He doubted the latter. There was still a serious mortality from puerperal septicæmia, but wherever medical authority and skill had been brought to bear there had been great diminution. Dr. Boxall had shown that puerperal fever had not diminished in England and Wales, though in lying-in hospitals it had almost disappeared. He divided the causes into, 1st, those which were essentially the product of the puerperal process; 2d, those which originated outside the body, as endo- and exo-genetic.

The endogenetic causes were, 1st, the serous effusion which occurred in the uterus and other pelvic organs during labor; 2d, the excess of lactic acid and other of the waste products of muscle action; 3d, the lochial discharge.

The products of change were eliminated from the blood, and when excretion stopped fever was generated; the lochial discharge when retained might putrefy out; as this depended probably on the admission of germs, it was closely allied to the exogenetic causes.

The question arose of how to obviate the endogenetic form. This must be aimed at by the proper conduct of labor. He thought that women of the better class were more liable to endogenetic forms than the poor; the latter being more susceptible to the exogenetic varieties. He absolutely condemned having lying-in wards in general hospitals. In the conduct of labor he advised the avoidance of unnecessary manipulation and the use of the tampon. He considered the careful use of the binder an important means of prevention, as not only did it tend to prevent hemorrhage, but it also prevented the suction of air into the vagina or uterus. He urged the preservation of the dorsal decubitus after labor for the same reason, and thought that injection and irrigation, as a general rule, were better avoided. Curetting, if done at all, should be practised with the utmost care, and he advocated giving regular doses of ergot, quinine, and other oxytoxics after labor, and the frequent cleansing of the external parts. Elimination must keep pace with absorption, otherwise one would get an endogenetic toxæmia.

As regards exogenetic causes, he drew attention to the fact that the curves of mortality of puerperal fever ran side by side with zymotic curves. All knew the danger of cadaveric poison, to which attention was first drawn by Semelweiss.

As regarded antiseptics, in the British lying-in hospitals they attached considerable importance to the frequent use of carbolic spray in the wards. He thought that one good effect of its use was that some of it was absorbed by the lungs, and so did good. Perchloride of mercury he used with caution, and considered iodine water the best thing as an intra-uterine injection.

In conclusion he observed that he had endeavored to raise a point which might be discussed profitably, and that the fact that a large number of women still died from puerperal septicæmia justified the choice of that subject.

Professor A. R. Simpson, of Edinburgh University, thought it better not to divide the causes into endo- and exo-genetic, but to look for a poison which had been introduced in every case. He thought that a division into different forms of the disease might be made, and that before calling a case puerperal septicæmia it was necessary to eliminate other diseases, as typhoid fever, which might coexist with the puerperium. He urged the importance of seeing that all who came in contact with puerperal women should be free from germs. He would put women in the best possible hygienic condition before labor. He would particularly avoid frequent vaginal examination, and thought that much of it might be dispensed with if abdominal palpation were more often carried out.

Dr. Cullingworth, of London, said that it had not been decided whether it was possible for the non-pathogenic organisms which were always present in the vagina to become pathogenic. It was a wholesome rule to act as though all puerperal fever were the result of infection from without, as this was the rule in nine hundred and ninety-nine out of one thousand cases.

As regarded antiseptic methods, he considered that douching was a very doubtful blessing, and it was much more important to be careful about asepsis of fingers; in douching, there was always a risk of carrying septic matter from the lower part of the canal to the upper. He rigidly discountenanced douching by any but a thoroughly skilled hand. All cases in which poisoning from absorption of perchloride of mercury had occurred were those in which it had been used for douching.

Dr. Jardine, of Glasgow, urged the importance of

allowing patients to sit up after the second day, at intervals, so as to afford a drain for the discharges.

Dr. Boxall, of London, drew attention to the fact that the mortality from puerperal septicæmia had not diminished as much as was usually thought. Such deaths can in the majority of cases be prevented. He drew attention to the large number of women who, though not actually killed, were permanently rendered invalids by puerperal septicæmia; sixty per cent. of the women of these islands were not attended by medical men at all, but by midwives. He urged importance of sufficient practical training for students, and would not discourage lying-in wards in general hospitals, as it was so much easier to teach practical details at the bedside. He would render aseptic the field of operation by a douche of 1 in 2,000 perchloride solution before the rupture of the membranes, made a point of using a douche given in this way at the beginning of labor, and one given by himself at the end.

Mr. Garrett Anderson, of London, thought we ought to aim at the extinction of puerperal fever, as it was always somebody's fault.

Dr. Sloan, of Glasgow, urged the importance of attending to the health of the patient during gestation, and the special importance of hand cleaning on most thorough principles; asked question as to when it was advisable to recommence attending midwifery after attending on a puerperal case, and gave an instance in which he attended a case half an hour after examining vaginally a woman suffering from puerperal septicæmia. He thoroughly disinfected hands and no harm resulted. He trusted to boiling to render aseptic instruments and other things which came into contact with patient.

Dr. Byers, of Belfast, said that in most lying-in hospitals the mortality from puerperal fever had been almost abolished, though all the measures taken aimed at the prevention of external contagion. He believed perchloride to be the best disinfectant for hands and instruments. He thought Dr. Cullingworth had gone too far in giving up the douche. He himself always used one if there had been a purulent discharge, or if the patient had run any risk of infection before coming into his hands. He did not believe that the disease could be carried by the atmosphere; he did not think time was an element in effecting purification after examining a case, but placed more faith in antiseptics.

Professor Oliver said that some of the causes of the disease were quite unavoidable, as, for instance, hemorrhage before labor. He thought that phlegmasia dolens was always septic. Among the unavoidable causes he mentioned cases of septicæmia which arose from salpingitis, the tube rupturing during labor, and he considered that this form should be treated by abdominal section.

Dr. Smyly, of Dublin, thought that one might neglect endogenetic causes, and drew attention to the fact that cases which were delivered in the street always did well. He did not believe in prophylactic douching; antiseptics were for the attendant, and not for the patient.

Dr. Aust. Lawrence would give a prophylactic douche, but would not use douching afterward; did not allow women to linger in labor; in the treatment of the disease used iodoform pessaries, twenty grains twice daily. When fever was present he would thoroughly wash out uterus.

Dr. Murdoch Cameron, of Glasgow, thought the worst cases were those in which there was no peritonitis, but high temperature, vomiting, diarrhœa, and quivering voice; to this last symptom he attached special importance. The only satisfactory treatment in his hands had been an intra-uterine douche of 1 in 2,000, with quinine and sodii salicylic. internally.

Dr. Pozzi, of Paris, thought the use of the finger for curetting, as advocated by one speaker, was most dangerous, especially to the operator. The use of the curette he considered valuable. If the uterus was large and there was fever, he always supposed that something had remained behind. He then, having previously ascertained the length and direction of the uterine cavity, used a blunt curette, holding the cervix with forceps. The curetting he performed with the greatest gentleness, especially attending to the mucous membrane near the cornu and washing the curette in carbolic after each stroke. He washed out the uterus immediately after curetting, with hot water containing two per cent. of carbolic, or perchloride 1 in 2,000, always after using the sublimate again washing out with plain hot water, and finally plugging uterus with iodoform gauze. It was remarkable how quickly the uterus began to diminish in size after this treatment.

Dr. Barnes in reply thanked the members for the interest they had shown in the discussion, and he was accorded a hearty vote of thanks for the part he had taken in bringing the matter forward.

Post-partum Ovariotomy.—Dr. Aust. Lawrence then read a paper with this title. He narrated ten cases on which he had operated: in all peritonitis had followed the labor, and the patients were supposed to have puerperal fever, the presence of the cyst not having been suspected during pregnancy. He drew the conclusion that when an ovarian cyst was discovered in the abdomen of a pregnant woman it should be removed as soon as possible, there being many dangers if it were let alone, whereas, on the other hand, pregnant women bore abdominal section well. Supposing the cyst were first discovered when the patient actually was in labor, he laid it down that one should endeavor to get the labor over with as little straining as possible, using forceps if admissible, and if symptoms of peritonitis appeared an operation might be performed; otherwise it would be better to wait till the puerperium was passed.

Dr. Pozzi agreed that it was a dangerous thing to have an ovarian cyst in the abdomen of a pregnant woman, the principal accident to which she was liable being the twisting of the pedicle. Sometimes, when the torsion was incomplete there was pain but no rise of temperature. He pointed out that sometimes the swelling in the abdomen was on the opposite side to that on which the cyst grew, and sometimes he had found similar symptoms caused by elongation of the pedicle, the cyst having been lifted up by the pregnant uterus, and formed adhesions high up in the abdomen upon which there was tension after the uterus emptied. The symptoms in these cases were chronic, and differed from the usually acute symptoms of torsion.

Dr. Byers thought that if a cyst were discovered near the end of term it would be better to wait until after labor before interfering.

Dr. Murphy, the President, had found pregnant women bear all operations well, and thought that in every case of pregnancy it was desirable to operate when a tumor was discovered.

Venter Fixation of the Uterus.—Drs. Leith Napier and F. T. Schacht gave particulars of twenty cases in which this operation had been performed by themselves and other operators; they advocated the employment of buried silkworm or catgut sutures.

Third Day, Friday, August 4th.

Extra-uterine Pregnancy.—Dr. Berry Hart, of Edinburgh, read a paper on "Ectopic Gestation." He said the most important point to determine was whether a pregnancy was intra- or extra-peritoneal. For some time it was believed that the former was usually the case, but of this there was no proof. It was thought, however, that an epithelial surface was necessary for the engrafting of the placenta, and that it fixed itself to the epithelial surface of the peritoneum. The guide to the nature of the gestation is position of the placenta and not of the fœtus. The results of the observations of many recent workers showed that advanced extra-uterine gestation was often extra-peritoneal, and that it began in the Fallopian tube, and developed in the broad ligament by enlargement of the tube and separation of the layers of the liga-

ment, and even up to full time it may remain extra-peritoneal. He drew attention to some observations he had made on the relative position of the fœtus and the placenta. He had found that the latter was most often in front or behind, and is not then displaced by the growth of the fœtus. The next most frequent place was for the placenta to be below the fœtus, and it was not then displaced by growth of latter, even after the fœtus had escaped into the abdomen. The most serious position of the placenta was for it to be above the fœtus. It was then pushed up by the growth of the fœtus even as high as the navel. The displacement of the placenta caused death of the fœtus and effusion of blood, and occasionally suppuration followed, and this explained the cases which ended in pelvic abscess. According to some, the placenta could not develop on connective tissue, but in his opinion this was an error. The placenta was made up on the one hand of villi, and on the other of connective tissue; he believed that there was no maternal epithelium covering the villi, and that an epithelial surface was not necessary for the attachment of the placenta. He had proved that the placenta in these cases was made up of villi on one side and connective tissue on the other. The treatment proper to one and all cases was abdominal section, and he thought that the older methods of treatment which aimed at causing the death of the fœtus had been quite given up.

As to the treatment of broad ligament pregnancy, he thought that we must lay aside the idea that the sac could be in all cases enucleated. If you removed the placenta there was risk of bleeding; if it was left, risk of putrefaction. It was better to remove the placenta and plug the sac, or if that was impossible, to remove the placenta, piecemeal, at intervals of a few days.

The Etiology of Ectopic Gestation.—Dr. J. C. Webster, of Edinburgh, read a paper on this subject. He said that of late the great importance of inflammation of the mucosa of the tube had been insisted on as a factor in the causation of the condition. Tait said, ovum never fertilized in the tube under normal conditions. The question remained as to where does spermatozoa meet ovum; it was generally held that the meeting took place in the tube, and in proof of this he instanced the fact that in some cases early pregnancy had been found in the outer end of the tube, the inner end remaining normal as regarded its mucous membrane. Another proof that ovum became impregnated in the tube was drawn from observations in comparative anatomy; in some animals the tube and the uterus form one cavity, the latter being bifid as we ascend the scale. The lower part of the double canal fuses until in man we have a single uterus with a tube given off from each corner. He did not think that denudation of the uterine mucosa by menstruation was necessary to insure a subsequent pregnancy and gave reasons in support of this view. He had found, on making a post-mortem of a case of tubal gestation, marked decidual formation in the non-pregnant tube, and thought that in some women there may be a decidual formation of the tube in parts, and that this may lead to the implantation of the ovum there.

Dr. Braithwaite, of Leeds, drew attention to the fact that the placenta in these cases sometimes completely absorbed.

Dr. Berry Hart gave a lime-light demonstration of photographs of frozen sections and of microscopical sections to illustrate the points of his paper, especially the fact that only one layer of epithelium lined the placental villus, and that, in his opinion, was fœtal in origin.

Dr. Boisleux, of Paris, read a paper on "The Drainage of the Pouch of Douglas," and showed a special tube he had devised for the purpose.

A Seasonable Epitaph.—The following epitaph was recently engraved upon a tombstone in Lincolnshire:

Here lies the body of Johnny dear,
Snatched away by the diarrhœa.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

BRITISH MEDICAL ASSOCIATION — USE OF THE ANNUAL GATHERING — NEWCASTLE INCIDENTS — EXPELLING A MEMBER—HYPNOTISM—SECTIONAL ADDRESSES—A CONVERSAZIONE PLUNGED IN DARKNESS—WATER SUPPLY—THE TEMPERANCE MOVEMENT AT NEWCASTLE—SERMON FOR MEDICAL BENEVOLENT COLLEGE — MEDICAL MISSIONS—ANNUAL MUSEUM—THE LONG VACATION—POSTPONEMENT OF THE INTERNATIONAL CONGRESS—CHOLERA APPROACHING—CASES IN SHIPPING—COST OF VIGILANCE—DANGER OF CASES BEING LANDED—AMERICA INSTEAD OF ROME—SMALL-POX—THE VACCINATION COMMISSION—OPHTHALMIA IN SCHOOLS—IRISH AND SCOTCH QUALIFICATIONS — EXAMINERSHIPS FOR THE ARMY—SHARES IN COMPANIES AS ALLEGED BRIBES—DEATH OF MR. A. E. DURHAM, JR.

London, August 8, 1893.

Now the hurly-burly of the Newcastle meeting is over one has time to glance at some of the smaller incidents and ask what is the position of this annual gathering as compared with others, or, if so inclined, what is the good of any of them? Well, this meeting will certainly rank among the more successful ones, and the officials and people of Newcastle deserve the hearty thanks expressed on all hands for their courtesy, hospitality, and determination to afford gratification to their guests.

As to the use of these meetings they must be regarded chiefly as opportunities for a brief holiday, and for meeting friends and acquaintances who are widely scattered. This is a sufficient excuse for the preponderance of amusements which invariably put the scientific programme in the shade. Doctors have, as a rule, less recreation than any other profession, and as they prescribe it for their patients may well show their faith in their treatment. Whether it is wise to crowd so much into one week is another question; but everyone is at liberty to attend or refrain from any of the entertainments, and it must be confessed that not a few give themselves reason to complain of fatigue. The continual round of gayety, the parties in which ladies are so enthusiastic, the dinners, music, ices, and grapes, tea and coffee, and open-air parties combine to banish *ennui* and make one forget the serious side of the meeting, except to seize the opportunity of hearing some prominent speaker or looking in at the section in which one feels most interest.

A rather unusual and unpleasant incident was the expulsion of a member. This step was taken on the proposition of the Council, who had tried the case *in camera*, and many members felt, and some expressed, the view that they ought to know something about the case. The officials, however, held that it was the custom for the Council to act and the general meeting to confirm. Surely it is not desirable in such a case for the general meeting to be asked to concur. It would be better for us to hear nothing of it unless by way of an appeal.

The report on hypnotism gave rise to some differences of opinion. One speaker said the whole thing was of the nature of quackery, and moved that the report lie on the table. Others held that the report was very moderate and cautious, and contained useful recommendations. Eventually it was received and the committee thanked for their services. This avoided the adoption without refusing all the conclusions. Everyone seemed to condemn public exhibitions of hypnotic phenomena, and many wished them to be prohibited by legislation. All agreed that females ought not to be hypnotized except in the presence of persons of their own sex.

This year some of the presidents of sections wisely refrained from giving an address. It would be well if all others follow this example. These addresses in the sections can be of no interest to general practitioners, and the specialists who attend can hardly need them, while the time is very limited. With more than twenty dis-

cussions and one hundred and thirty papers to be read, or taken as read, the time is utterly inadequate—only four hours on Wednesday, four on Thursday, and an hour and a half on Friday. There is a surfeit of addresses, and those who preside over sections might well spare us. All honor to those who did.

An annoying misadventure somewhat spoiled the Mayor's *conversazione* on Wednesday evening. It was held in the Natural History Museum, the size and contents of which are alike remarkable. Visitors began to arrive by 8.30 P.M., and continued for an hour to stream in. In the first room is the zoölogical collection, in the second a collection of birds, in the others geological and ethnological collections, and in the gallery original drawings by Hancock and Bewick. While these were being inspected by numerous admirers, and the crowds of other guests were chatting gayly, the Museum was suddenly plunged in darkness! The electric light had failed. A feeble flicker or two followed, hailed with cheers, but that was all, and the startled multitude began to grope their way out by the light of two or three gas jets, which, I understand, had only been fixed a week before. It was an unhappy *contretemps* for the mayor and inhabitants. Everyone felt sorry for them, but no one grumbled, and not a few seemed to enjoy the humor of the situation.

There was some talk of a more terrible failure for Newcastle. It was said that the town only had sixty days' supply of water, and that the tanks had a decrease of 1,578,477,770 gallons compared with this time last year. The sources of supply are, however, still running, and the effect of the dry summer is likely soon to disappear amid autumnal rains.

The temperance movement holds a strong position in the north of England, and the local society of Newcastle was well to the fore at this gathering. Besides this, the Medical Temperance Association held a meeting, which was well attended. Thus members had an excellent opportunity of hearing at first hand the views of their medical brethren, and listening to the eloquent advocacy of Professor Victor Horsley, Dr. Ridge, and other well-known leaders in this movement.

The Bishop's sermon was given in the beautiful cathedral of St. Nicholas, and he placed before the assembled members the claims of the Royal Medical Benevolent College, for which the collection was made.

Medical missions were the subject of an excellent demonstration in the Concert Hall. Dr. Valentine, who has spent more than thirty years in India; Dr. Maxwell, formerly of China, now of London; Dr. Fry, of the Edinburgh Medical Missionary Society, and Miss Taylor, the intrepid Thibetan traveller, took part in this meeting, which was presided over by Professor Simpson, of Edinburgh. We have made considerable progress in medical missionary enterprise of late years, but I believe America is still ahead of us in this matter.

The Annual Museum partook of the general character of its predecessors. Some interesting demonstrations were given in the scientific part, and the more commercial side was represented by the exhibition of many instruments, foods, and drugs, while a mass of what the vendors call "literature" was distributed—nay, pressed upon all comers. Although many members returned to London from Newcastle, the majority have again left, or are leaving, within a day or two. Those, too, who did not go to Newcastle are rapidly disappearing, and the exodus for the autumn vacation will soon be complete. Of course, there are still plenty of doctors hard at work in London, in spite of the common statement that "everyone who is anyone is out of town." They pursue the even tenor of their way, and can usually find consultants when they want them, for not a few take care to be at home while their friends or rivals are away.

London, August 12, 1893.

You will have learned by cable that the International Medical Congress has at length been definitely postponed until April. To some this will come as a surprise after the several rumors that have been so positively contradicted. But those who observed the advance of cholera were quite prepared for the announcement. The "sanitary anxieties of the European states," as the official statement phrases it, would probably prevent a successful congress, for cholera has already invaded Italy, and her government have, after much hesitation, resolved to act on the Dresden Convention by communicating cholera news to the signatory powers. There were ninety cases at Naples in July, and from five to fourteen deaths daily this month. A few scattered cases are also reported from other parts of the peninsula.

Here in London we are all on the *qui vive*, though a general spirit of confidence prevails that our sanitary precautions are sufficient. This feeling has been reinforced rather than diminished by the arrival of a vessel in the Thames with a case on board, the patient having been removed to the hospital and the vessel dealt with under the cholera orders and no infection having occurred. Similar occurrences in the Mersey and the Humber have been dealt with in an equally satisfactory manner. Other cases are to be expected, indeed some have already occurred, at our ports, and if only we are able to escape from an epidemic we shall be rewarded for our sanitary work and expenses. Two points are attracting attention in this respect. One is the great cost incurred by the ports, and the question whether they ought not to be aided by the rest of the country, which naturally benefits by their vigilance. The other is the possibility of a case being landed on our shores at some place distant from sanitary assistance and how this danger is to be averted. Both these questions have been freely discussed both in public and at private gatherings, and the sentiment of the profession seems to be to support the medical officers of health in all their demands.

The postponement of the International Congress of course involves a similar result as regards the Hygienic Exposition and other fixtures. Some who had arranged to be at Rome, and are yet free, are talking of how to take their holiday. Many are off to the hills or the sea, but a few are still undecided and perhaps some may substitute a voyage to America. It would be easy to do Chicago and Washington, and the Pan-American Congress would no doubt be interesting. I should be glad indeed if it were possible for me to cross the Atlantic and enjoy the hospitality of my many American friends and pupils. Small-pox is still with us, and in the country seems inclined to spread. In London, however, there is a diminution; forty-three fresh cases were notified last week, and two hundred and twenty were under treatment. These numbers are lower than for some months past.

The Vaccination Commission "drags its slow length along." For above four years it has been sitting and considering how small-pox has prevailed. There is a growing impatience at the delay. The commission has heard at great length anti-vaccinationists, unqualified practitioners, and even herbalists. Surely it is high time they were able to digest the evidence and formulate their conclusions in a report.

A report by Mr. Sydney Stephenson, on the ophthalmia that has prevailed more or less constantly in the parish schools of St. Pancras recommends alteration of diet, ventilation, and the washing arrangements, while it is urged that all acute cases should at once be sent to the Isolation Infirmary. In a recent inspection a number of the children in the school were found to be suffering from the subacute form of the disease, and as they are centres from which it will spread, the medical officer should have authority to exclude from the school every child affected with any form of ophthalmia.

The Scotch and Irish corporations are taking up the cry of their diplomates being boycotted on a fresh ground, and the discontent has made itself felt in Parliament.

It seems that the Secretary for War, by way of making some qualification for examinerships of the army medical services, proposed to limit such appointments to the past and present examiners of the two London colleges. It

was an unfortunate limitation, though no doubt made in good faith. The excluded bodies naturally cried out for their share of good things, and will, of course, get it. I shall be sorry to see the appointments confined to any examiners; for although it is plausible to say these gentlemen ought to have served their apprenticeship in the art of examining, it is well known that some have held such offices for long periods whose aptitude for the duty was by no means conspicuous, and others have suffered in their reputation as professional men and gentlemen by holding positions for which they were evidently unfit. I would recommend the War Minister to abolish all restrictions. There are plenty of able physicians and surgeons to be found who possess every qualification for the duty, and the heads of the medical departments could easily select them.

There is another case in which the old territorial distinctions of our qualifications give rise to discontent. The Royal College of Physicians was for generations a metropolitan corporation. By extending its operations it has embraced the provinces, and now provincial physicians claim a share of its offices. There has been no great objection to this, and some fellows have been appointed examiners although residing at a distance. So we hear congratulations on the liberal tendency of this ancient corporation. It is early days for this. When liberality is displayed in the admission to the fellowship, or when members and licentiates obtain some rights in the college, it will be time enough to pay attention to the self-congratulations of those who occupy the position of monopolists.

Some medical men have recently incurred opprobrium by accepting, or at any rate not refusing, a "founder's share" in a food company. Although the letter offering them stated they were "fully paid up," these words did not appear on the face of the shares, and the liquidator (for the company quickly passed into liquidation) sought to make the holders liable for the amount. The judge granted an application to remove the names from the list of contributors, but refused costs and made some strong observations on the apparent acceptance of what looked like a bribe to prescribe the company's wares. It is certainly a pity to see such an imputation incurred, but I think that these men were, perhaps, more sinned against than sinning, for I know of one case in which an attempt by a company to palm off shares on a doctor, in a more subtle manner still, was only defeated by the greatest circumspection. Every possible method of inveigling men into accepting some inducement to prescribe certain foods and drinks is resorted to by cunning traders, and no wonder these latter occasionally score a success. None the less is it a sad thing that a few thoughtless or unsophisticated men should thus be made to furnish material to newspaper writers for sneers at the profession. On the other hand, the outcry of a medical journal that such conduct is "infamous," is just a little too pronounced, considering the advertisements in its pages and the analytical puffs in its columns.

I am sorry to report the death of Mr. Arthur Ellis Durham, from diphtheria, caught in the course of his duty as resident at the Fever Hospital. He was the eldest son of the well-known surgeon of Guy's Hospital, and a distinguished alumnus of Guy's and Cambridge.

A Modified Cannon-ball Treatment of Obesity.—Dr. Felkin, of Edinburgh, uses an India rubber ball, three and one-half inches in diameter, almost filled with five and three-quarter pounds of shot, in the treatment of chronic constipation, anæmia, and obesity. The patients are instructed to roll the ball from right to left round the abdomen for five or ten minutes night and morning. One of his patients had lost ten inches in girth after five months' regular use of it. A rather smaller ball, with a less quantity of shot, he finds very useful in inducing a regular action of the bowels in young girls, who so frequently suffer from habitual constipation; this plan obviated the need for constant dosing.

EXCLUSION OF IMMIGRANTS BECAUSE OF FAVUS.

To the Editor of the Medical Record.

Sir: I have seen it stated several times in the daily papers of late that children affected with favus have been refused admission to this country, and were sent back by the authorities of this port. This, if true, seems to me to be both inhuman and not at all warrantable from a medical standpoint.

1. Favus is not very easily communicated from one child to the other. It requires not only close contact, but also a general atmosphere of uncleanliness and neglect. Ringworm of the scalp, on the other hand, spreads far more readily than does favus. The latter is more amenable to treatment. The differential diagnosis between ringworm of the scalp and favus is by no means always easy to make without the aid of the microscope. Why is favus sent back and ringworm admitted?

2. What is done for the cases of favus now existing in this city? It is wrong to suppose that the disease is strictly peculiar to certain provinces of Russia and Poland. There are quite a number of cases in which American boys have contracted it from pet animals (cats and mice). I have myself seen one such case and reported it to the Medical Record. At the Randall's Island Infant Asylum there are always some cases of favus which apparently were not imported. Is there a dispensary in this city where favus is treated properly, *i.e.*, where epilation is practised thoroughly and by trained attendants, as is done in the Hospital St. Louis in Paris? It is almost impossible to find anybody in our large and well-equipped city institutions who has the time or inclination to follow out this tedious but necessary therapeutical measure. In a paper read at the fortieth annual meeting of the American Medical Association, in 1889, I advocated the establishment of a special service for the free treatment of vegetable parasitic diseases of the skin in one of our city dispensaries. As far as I know, no step has as yet been taken in this direction. The sending back of a few "bad" cases of favus either demonstrates our inability to cope effectually with this disease, or, at best, it is one of those prophylactic half measures, which "will but skin and film the ulcerous place while rank corruption raging deep within infects unseen." (Shakespeare.)

Yours very truly,

Fred. J. Leviseur, M.D.

"Hoffman Arms," 640 Madison Avenue.

A POSSIBLE EXPLANATION OF THE VICTORIA DISASTER.

To the Editor of the Medical Record

Sir: Among the different narratives of the recent destruction of the British war-ship Victoria that have met my eye, I have seen no allusion to the possibility of incipient insanity on the part of the unfortunate admiral, as an explanation of his strange orders and subsequent vacillation in time of peril. I once had under my care a patient whose experience may possibly throw some kind of sidelight upon this disaster.

My patient was a lake captain, about forty-eight years of age, a seaman from birth, who owned and commanded the ship that he sailed. One day, voyaging in broad daylight, as his bark was approaching another, bound in the opposite direction, he suddenly ordered the wheelman to put the helm down when it should have been put up. The mate, regardless of provoking the wrath of the captain, rushed to the wheel, reversed its spokes, and thus avoided the collision that would have otherwise occurred. To his surprise, this action was ignored by the captain, and nothing was said of it until subsequent events recalled the incident.

The next symptom presented itself one day as the ship was leaving port. The captain's place at such times is upon the forecastle, or other elevated place, whence he can issue orders to the crew and to the man at the wheel.

To the surprise of everyone, right in the mid-passage through the narrow and crooked channel, the captain left his post, went down into the cabin, and curled himself up in his berth for a comfortable nap. He, however, managed to run his vessel safely through the shipping season; but when navigation was closed by winter, he began to exhibit decided symptoms of melancholia. This continued till the following spring, when his cheerfulness returned, and he embarked again for the usual summer voyages. Very soon after leaving port it became evident to all that his mind was deranged, so that he had to be deprived of command and put on shore. He rapidly developed the phenomena of "circular insanity," went voluntarily to an insane asylum, and died there in less than three years from the commencement of mental failure.

HENRY M. LYMAN, M.D.

CHICAGO, ILL.

THE NON-REGISTRY OF BIRTHS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: On page 719 of the MEDICAL RECORD, issued June 10th, is an article headed, "The Diminishing Birth-rate of the United States."

We know it is an easy matter to learn how many deaths occur, for the reason they are not allowed to bury the body without a permit and record. Now, I believe it is quite different in reference to the recording of each birth. For example, in the village where I now practise, there are about three hundred Polish families, and they are nearly as prolific as rabbits, but no record is made of the birth of these children. They are always attended by some old midwife who is not compelled to report the birth. I will venture to say, there are few physicians, in the smaller towns and country places who cannot call to mind families who never record the birth of their children. Therefore I, for one, would be pleased to know how any man can give the ratio between the birth and death rate of the United States. It is an injustice to the medical profession of this country, to record every death and not every birth, and we ought to compel foreigners and natives alike to record the births of their children.

New Instruments.

NEW INSTRUMENTS FOR THE REMOVAL OF ADENOID TISSUE.

BY W. H. BATES, M.D.,

NEW YORK.

THE instruments have been in almost daily use for eighteen months, and have proved very satisfactory. The instruments are drawn a little less than one-half the actual size.

FIG. 1.

The forceps can be readily introduced behind the palate on account of their conical shape, and the gagging of the patient does not materially interfere with their use. They reach parts above and behind the Eustachian tubes. They are made of sufficient strength to cut away the adhesions and dense fibrous tissue in the region of the Eustachian tube, which often causes chronic deafness in adults. The forceps come together first at the apex, like a pruning-hook, an advantage in removing tissue from the outer portions of the vault.

Those forceps in use which have the cutting edge on part of the blades only, when used often cause pain and soreness which may last a number of days after the operation. If the adenoid tissue grasped extends below the cutting edge, it must be pulled off, causing a traction on the neighboring parts which is painful. In these forceps, the cutting edge extends all the way around, and when properly made will bite out an oval piece from ordinary writing-paper like a conductor's punch—no traction occurs and the operations are painless (patients' statements).

The palate or Eustachian tube will not be injured ev n when the patient gags, if one presses back against the bone before closing the blades.

This instrument (Fig. 2), used through the nose, is of value in removing adenoid tissue in cases which object to operations through the mouth. The instrument can be used through the nose where an Eustachian catheter can be passed. It is curved sufficiently to reach parts of the vault more than half an inch below the level of the floor of the nose. The tip can be turned in all directions, and the curve does not interfere with the working of the instrument when the tip is turned. The instrument is strong enough

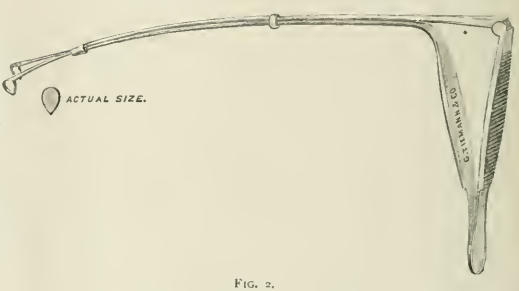

FIG. 2.

to remove the fibrous tissue found in the vault in adults. The cutting blades are similar to the first instrument, but smaller. This instrument is also of value in removing nasal hypertrophies, especially from posterior portions of middle and inferior turbinated bones.

I am indebted to Mr. Childs, of the firm of G. Tiemann & Co., for many valuable suggestions.

131 WEST FIFTY-SIXTH STREET.

A NEW LACHRYMAL PROBE.

BY G. W. CALDWELL, M.D.,

NEW YORK.

LATE RESIDENT SURGEON NEW AMSTERDAM EYE AND EAR HOSPITAL; INSTRUCTOR IN OPHTHALMOLOGY, NEW YORK POLYCLINIC.

I WISH briefly to invite the attention of the profession to a new design of lachrymal probe which I have found to be a very satisfactory instrument. It consists, as indicated by the accompanying figure, of a small wire staff 11 ctm. in length, in the middle of which is soldered a plate for convenience in handling. On each end is a bullet-shaped tip 1 ctm. long, with a conical point and abrupt shoulders as in the urethral bougie à boule. These tips are graded, as are Theobald's probes, in successive numbers, each unit of which represents one-fourth mm. of diameter. The shoulders are intended to emphasize the properties of an obstruction, while the length is sufficient to allow it to be retracted into, and held by, a stricture, for the purpose of dilatation. A complete set comprises seven double-ended probes numbered from 1, which is the staff alone, to 14, the largest size. They are made, according to my design by Tiemann & Co., New York.

The advantages of the probe are that while, for the purpose of dilatation it possesses all the essential properties of Bowman's, Theobald's, or any other now in use,

it also affords the additional advantage that with it a diagnosis of the location, length (allowance being made for the length of the tip), calibre, and character of an obstruction may be accurately made. The small size of the staff avoids traction at the inner canthus, and therefore the pain of its passage is less. The entrance of the probe into the space between the inferior turbinated body and the outer wall is immediately manifested by the loss of resistance. It is not therefore necessary to carry it to the floor of the nose to be assured that it is in the nasal space.

In preparing wet anatomical specimens I have observed that not infrequently the inferior turbinated body rolls upon itself in such a manner as to lie in the course of a

probe projected through the nasal duct. When we remember that the nasal duct is only one-half to three fourths of an inch in length the reasonable suspicion must arise that this anatomical arrangement may possibly explain some of those so-called "very firm strictures which are occasionally encountered at the lower extremity of the duct," to overcome which probes of such extraordinary strength and length have been advised. In other cases the antral wall encroaches so far upon the nasal space that an ordinary probe on its downward course impinges upon the outer wall at an acute angle, when, if the force is continued, the periosteum is lacerated and pockets formed which complicate the case. These accidents can hardly occur in the use of this probe, as its escape from the nasal duct is immediately indicated, and we need not be seriously concerned about what the probe may encounter further down.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 26, 1893.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	40	6
Scarlet fever	30	6
Cerebro-spinal meningitis	2	5
Measles	80	11
Diphtheria	104	27
Small-pox	2	0
Cholera	0	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

Gratitude Does not Last.—In a recent address to medical students, delivered by Dr. Kelley (*The Cleveland Medical Gazette*), the following pertinent remarks occur: "There are those who seem to imagine that the deified dignitary known as the physician is borne aloft in an atmosphere unknown to common mortals, fragrant with the incense of grateful hearts. Now, let me advise you—any among you who may realize your desire to become a physician—if ever the time comes that gratitude is poured out upon you, as it will be, enjoy it—pause and enjoy it as you would the perfume of a fragile flower—for it will not last—it will not last. Perhaps I should not say to young people so cynical a thing, but I doubt the very existence of lasting gratitude. As a matter of fact the doctor is often treated with basest ingratitude. Why, I know numbers of people who owe to my efforts their lives or limbs, or the use of their faculties, as surely as if I had plunged into a swollen torrent and rescued them from drowning, or had dragged them timely from before the wheels of the lightning express, and who not only owe, and intend always to owe, a modest bill for professional services, but who never lose an opportunity to attack the reputation of their benefactor. Every physician has the same experience, and it seems inherent in the ingrate patient to slander. Probably it is in defence of himself before his accusing conscience, if such creatures have a conscience, or before some neighbor, that the wretch feels compelled to trump up some lie as an excuse for his conduct. He will stand up barefaced and say he "was not treated right," when his own presence in this life is a denial of his assertion. If he had not been treated right his mean little soul would ere this have left his body and gone where—no good spirits go."

Salve for Rheumatic Pains.—*L'Union Médicale* gives the following:

℞. White wax	5 grammes.
Adeps	15 grammes.
Add to this, when sufficiently cool,	
Chloroform	3 grammes.

A layer of this preparation is to be spread upon a compress held in place by a bandage. Wax is added to the ordinary base to retain the chloroform longer and thus obtain a greater analgesic effect.

The Dangers of the Barber Shop.—The report of a case of tuberculosis of the bearded face will direct attention to the danger of transmission of tuberculosis through the intermediation of the instruments used by the barber. To prevent such an occurrence each individual should have a separate brush and cup and napkin and razor. If one razor is used in common it should not again be used before having been placed for a short time in boiling water and dried, while persons who present themselves to the barber with diseases of the bearded skin should be advised to consult medical men.—*Medical News.*

The Transmission of Cholera by Means of Flies.—It has been proved that tubercle bacilli are found in the excreta and bodies of flies that have been feeding on phthisical sputa, and it has been suggested that it is possible for tuberculosis to be spread by these means. In the *Centralblatt für Bakteriologie und Parasitenkunde*, Band xii., p. 25, is a communication from Dr. Sawtschenko, who has found that cholera bacilli possessing all their virulent properties can be demonstrated for at least four days in the intestinal canal and dejections of flies that have been feeding on the stools of cholera patients or on the intestinal contents of those who have died from the disease. He also produces evidence to show not only that the bacilli pass through the intestinal tract of flies, but also that during the passage actual multiplication takes place. It is likewise an interesting fact to observe that the longer the interval of time which is allowed to elapse between the period of infection and the examination of the dejecta the smaller is the number of saprophytic organisms present and the larger that of the cholera bacilli. Control experiments were made with flies which had been prevented from incurring chance inoculation, and negative results followed. Dr. Sawtschenko, therefore, is of opinion that flies may act not only as carriers of the morbific agent of cholera, but also as hosts of the bacilli.—*The Lancet.*

Idiosyncrasy in the Action of Quinine.—Dr. Khaikhusara Jivanji reports in the *Indian Medical Record*, the case of a lady suffering from diabetes for whom he prescribed a mixture containing only a grain and a half of the sulphate of quinine, to be taken thrice daily. Immediately after taking the first dose she felt a troublesome itching on the lower lip, on the lobe of the left ear, and on the dorsum of the left foot, resulting, in about an hour's time, in inflamed patches with troublesome irritation. This irritation passed off in about forty-eight hours, leaving dark spots which still exist. She stated that when-

ever she took quinine in any form the result was the same. On one occasion I prescribed for her Easton's sirup in half-drachm doses, with the same result, but this time the left lobe of the ear and the left cheek alone were affected.

Vomiting during Anæsthesia may be arrested by compression of the phrenic nerve and vagus. Dr. Joos, of the Cantonal Hospital, at Winterthur, applies compression with the thumb on the left side, immediately above the sternal end of the clavicle. The hand is held flat on the thorax, and the thumb is parallel with the clavicle. In Dr. Joos's experience the vomiting and hic cough forthwith cease. He also suggests that this treatment might be useful for the relief of sea-sickness.—*Medical Review.*

A Case of Supernumerary Spleen.—Surgeon G. Harrison Younge reports the following case in the *British Medical Journal:* Private M. D—— was admitted into the Station Hospital, Malapuram, March 28, 1893, suffering from enteric fever. From the first the range of temperature was very high, and the symptoms very severe. He died on April 4th, from hyperpyrexia, his temperature at the time of death being 108° F. The post-mortem examination showed unusually deep and extensive ulceration of Peyer's patches and the solitary glands, several of the ulcers varying from one to one and a half inch in diameter. There was hypostatic pneumonia of both lungs. The left lung was firmly adherent to the parietes and diaphragm over its entire surface. A mass of calcified tubercle as large as a hazel-nut was found in its apex. The spleen weighed fifteen ounces, and was congested and friable. Lying almost in contact with its lower border was a supernumerary spleen. The latter was one and a quarter inch in diameter, was perfectly circular in shape without any attempt at a hilum, was attached to the spleen by a distinct fold of peritoneum, and was supplied by a special branch from the splenic artery. On being cut into it presented the usual appearance of a spleen which was congested and friable.

A Phenomenal Fee for an Operation for Rectal Fistula.—It is not perhaps very extensively known that Louis XIV. of France was one of the first to undergo the ordinary operation for rectal fistula—that is, of slitting up the fistulous tract with a bistoury. In the month of January, 1686, or more than two hundred and seven years ago, great consternation was caused in the Royal *entourage* on account of the king's great complaint of pain in the region of the anus. The sudden seizure was surrounded with a perplexing amount of mystery, owing to the fact that every one appeared to be ashamed to mention its fundamental character. The concurrence of opinion, however, among the attending physicians and surgeons was that the disease was an abscess in the neighborhood of the anus, and the suggestion was made to lance it; but as nobody seemed to know what the result of this would be, the king declined to submit to the treatment. However, after the lapse of twenty days, wiser counsels prevailed, and the king agreed to have the abscess opened by means of caustic. This was safely accomplished, and soon the bald truth presented itself to the surgeons that they had a fistulous tract communicating with the rectum to deal with. Now the trouble began. The whole court put its head together in order to determine what was best to be done, and to suggest remedies. So many enterprising suggestions were made in this direction that it was considered advisable to retain the services of four patients with fistula of the rectum, and these were taken from place to place for the purpose of submitting to the various forms of treatment with a view to testing the value of the latter before they were applied to the king. Sad, however, to relate, a year went by without a single cure resulting from any of these experiments. In this trying dilemma, Bessiers—a celebrated surgeon of the day—was called in, and in an aphoristic dictum he informed the king that "all the remedies in the world are of no account without an operation." This opinion helped matters forward considerably. The king summoned Felix—a barber-surgeon—to his presence, and a consultation was held as to the best method of operating. The ligature was greatly in vogue at the time, but Felix pronounced for the bistoury, and promised the king that if this plan were adopted a speedy cure would result. Nevertheless, Felix had never performed the operation himself; in order, therefore, to get his hand in, he operated on all the fistulous patients in the hospital, and successfully. The great day arrived, Monday, November 18, 1687. At daybreak the apothecaries entered the King's bedroom and gave him an injection. A little before seven the operation was performed without difficulty; lint was applied to the wound, and covered with an ointment of yolk of egg and sweet oil, and fixed by a pad and bandage. Then the rejoicings took place. Every one praised the bravery and firmness of the king. All his courtiers called on him at the earliest opportunity, and every one of them who had a fistula or pile desired to be operated upon immediately. Indeed, it was stated at the time that "the entire court had its tail examined in the hopes of being operated upon." But to make a long story short, everything turned out well in the end. Plugging the wound from the bottom was not known in those days, and therefore, owing to too rapid healing, it was found necessary to reopen the wound; but after this a complete cure resulted. The honors were chiefly due to Felix: the king gave him 300,000 francs, made him a present of a landed estate, and also ennobled him with a title! In comparison with the fees which surgeons are able to get for such an operation in the present day, the only conclusion possible is that surgery must be "played out."—*Medical Press.*

The Doctors of Hawaii.—According to the description of native Hawaiian doctors, given by Dr. H. Stedman, they are dependent, almost entirely, upon luck and strongly constituted patients for the few cures they seemingly effect. Dr. Stedman is an Australian physician who has made a tour of the Sandwich Islands; he tells some amusing stories about his intercourse with his Hawaiian brother-practitioners He says they are unconscious frauds and believe thoroughly in their ability to heal. Their treatment consists chiefly in prostrating their forms and supplicating the deities for their divine assistance in dissipating the infernal spell which holds the unfortunate in bondage. They have a vague idea of the utility of massage; but they administer this treatment so brutally, with their clenched fists, that the poor patient usually prefers death to its continuance.—*Medical Fortnightly.*

Medicines in the Days of Queen Mary.—Not many remedies of Queen Mary's time retain a place in the modern pharmacopœia. Cardano recommended bark of Indian wood, cinnamon, caryophyllum, colocynth, camphor, cyclamen, viola, turpentine, hops, anise, senna, poppy, mustard, myrrh, wormwood, agrimony, lichen, privet, rue, raisins, hyssop, crocus, marjoram, scabious, figs, honey, and many more; and he earnestly urges the use of a remedy which he had tried himself for breathlessness accompanied by bad cough: Take the lungs of a fox and forthwith wash them with wine and dry it in a furnace to a cinder: powder, and mix well with the yolk of an egg. Among his external remedies, one which was evidently a prime favorite, was that which he applied over the sutures of the skull, and especially the coronal, and which he found a grand remedy for bringing away the humors of the brain. It was composed of Greek pitch and ship's tar, white mustard, euphorbium, and honey, sharpened, if necessary, by the addition of blister fly. He had unbounded faith in the efficacy of elaterium—two grains dissolved in four ounces of goat's or cow's milk and as much water, this to be drawn through the nostril when the patient was fasting. He had found that when this remedy was used a very copious discharge of humor took place from the nostrils.—*Blackwood's Magazine.*

FURTHER CONTRIBUTIONS TO THE PATHOLOGY AND THERAPY OF NEURASTHENIA SPINALIS.[1]

By LEONARD WEBER, M.D.,

NEW YORK.

In a paper entitled "The Present State of Treatment of the Chronic Diseases of the Spinal Cord, and Especially of Neurasthenia" read by me before the Neurological Society of the city of New York last year, and published in the Medical Record, May 28, 1892, I endeavored to give a *résumé* of the subject from the time of Beard, who coined the name and drew a clinical picture of the disorder which has not been surpassed by other authors. From a not inconsiderable clinical experience of my own I related some interesting cases of neurasthenia gravis, and in concluding showed, I believe, that in the way of curing it we had not made much progress, but had learned to understand the general character and management of the disorder better now than we did some years ago.

In taking up again the study of the subject it seems to me that there are even now more routine and set modes of treatment for neurasthenia than nice discrimination and careful adaptation of remedies to the special indications of individual cases. Given, for instance, a case of neurasthenia from sexual or other causes, and the patient's urine showing a specific gravity of 1028 or more and highly acid reaction, it will be always latent gout with certain practitioners—malaria having taken a back-seat for the present. Buffalo or Londonderry lithia or Vichy water will be given freely, and the patient be ordered to follow a particular diet, take Turkish baths, and special gymnastics. In the great majority of such cases it is the asthenic neurosis that produces the functional disturbances of the abdominal viscera through deficient innervation of the same, making perfect digestion and assimilation impossible. The presence of an excess of uric acid being then often an effect and secondary cause of nervous irritation, the treatment prescribed may relieve the symptoms of acid dyspepsia, etc., but will not remove the underlying disorder.

There are others who will apply their treatment to the central nervous system at once, and choose electricity in one of its three modes of application to the exclusion of almost all other remedies. The electric current will relieve the neuralgias, dys- and par- æsthesias so often associated with neurasthenia, and it will do a little more in the way of producing a refreshing and tonic influence upon the patient when applied in the morning hours, during which his condition is generally lower and more wretched than at other times of the day; but those effects will soon pass away, and as often as repeated pass away again. However, electricity is a good stimulant and tonic in these cases, it will maintain its place in the order of remedies good to help along, but it does not cure them.

Others, again, put all their faith on hydrotherapeutics. If applied judiciously and for a sufficient length of time, under the supervision of an expert, at a sanatorium located in a first-rate climatic resort in a dry and healthy mountain-valley, not more than 1,500 to 2,000 feet above the sea level in the northern parts of the United States, the results obtained by hydrotherapy in properly selected cases will be good, even very good. Yet there are cases of neurasthenia enough to be met with, in which either the blood-circulation is too feeble or the reactionary power not strong enough to bear such treatment to begin with, aside of certain idiosyncrasies or complicating catarrhal or renal troubles by which it may be positively forbidden. To follow this mode of treatment without exception would be as illogical as to practice exclusively either of the first two, and would lead to frequent disappointments.

In dealing with so complex a neurosis as cerebro spinal neurasthesia it goes without saying that we must carefully individualize and minutely examine into the etiology of a case and the mode of life of the patient before we can map out a plan of treatment which is likely to do him good.

First in the order of frequency among the etiological factors I should like to place sexual disorders, such as masturbation more or less prolonged in early life in both sexes, though more frequently in the male than the female. This abuse, with its frequent discharge of a highly albuminous liquid, nervous excitement, and concussion of the brain and spinal cord by the sexual orgasm often repeated, when early begun and continued for some years, as we often learn from the confession of the unfortunates, must necessarily hurt the cerebro-spinal nervous system, in fact the entire organism, and retard and impede its growth to healthy, vigorous manhood; it must and does affect the intellect, enfeebling memory, sound judgment, and will power, though much less so in those who come of healthy and vigorous parents than in those afflicted with the neurotic taint.

From the extreme degrees of mental and physical bankruptcy caused by excessive and prolonged indulgence of the pernicious habit, from which no such restoration of the abilities can be had as to allow the victim to be on equal terms with able and vigorous men in the active pursuits of life, down to mild degrees of mental unrest and pretence of physical woes due to sexual errors that were as quickly stopped as begun, all shades and varieties have been seen and noted. In very young children epilepsy and idiocy may be induced, the adolescent will be made a weakling by it, and not infrequently remain so, the full-grown man when led to the vice in or out of married life through various and often peculiar circumstances, will suffer more in his mind and general moral tone, and be made miserable by cerebral asthenia.

Now, the first thing to be done in cases of sexual neurasthenia is to put a stop to the ever-present reflex excitability by the bromides. From long experience I give the mixture of the three bromides, in preference to a single one of the salts, and generally succeed by them alone or after adding the daily cool sponge-bath, or tepid half-bath, or wet sheet with body-friction on rising. The prostatic portion of the urethra in many cases needs attention, and the steel-sound passed three times a week down and a little beyond the caput gallinaginis of the prostatic portion, and kept in position for five minutes will soon diminish the hyperæsthesia of those parts. The patient will soon learn to pass the sound himself, but he must be careful not to enter the bladder with it. In cases with very great irritation of the prostate, and discharge of a glairy fluid on slight provocation, I have found it useful to use, besides the sound, injections of mild solutions of tannic acid or sulphate of zinc with any of the syringes in vogue for posterior urethral injections. Where the bromides would not help, or were not well

[1] Read before the American Neurological Association at their nineteenth Annual Meeting, July 26, 1893.

borne by the stomach, atropia, in doses of from $\frac{1}{200}$ to $\frac{1}{100}$ grain given daily have been of service. Within three months generally the patient's condition is so far improved that, iron when indicated, or the hypophosphites with cod liver oil may be given. These remedies and suitable hydriatric procedures, and the further but less frequent use of the steel sound I have frequently continued with for two and three and more years, with timely interruptions, to be sure. Most of these patients are also more or less troubled with atonic dyspepsia, associated with much eructation and flatulence and constipation, the latter much more often than diarrhœa, which again we encounter more frequently in other forms of neurasthenia. These intestinal troubles are easily relieved by proper and nutritious food with a preponderance of meat, and by well-known drugs, of which nux vomica with bismuth and soda before and a little muriatic acid after meals, I am in the habit of prescribing oftener and with better results than anything else. In neurasthenic dyspepsia, as well as in many stomach disorders of persons of sound nerves, we shall often go far from the truth if we simply suppose that a patient with the rational symptoms of chronic catarrh of stomach must have chronic gastritis, based upon anatomical structural lesions of the organ. Our methods of examination are now better than they were, and, in most cases, will not leave us long in doubt about the presence of organic change, but, so long as nothing serious is disclosed, our patient will do better by getting the benefit of the doubt, and the proper treatment for functional disorder.

We have learned of late that functional disorders of the stomach, *i.e.*, insufficient action which may be classified as sensory, motory, or secretory insufficiency, or combinations of them, are far more frequent among the causes that underly dyspepsia than the so-called chronic gastric catarrh. To properly diet such patients and correct and improve their conditions and surroundings and mode of life will be apt to help them and cure their dyspepsia, while special and active treatment of the organ, which is not the seat of catarrhal inflammation at all, will do harm. I am also in the habit of using electricity in the form of the galvanic current, in cases of sexual neurasthenia, where its use is indicated by local pains or hyperæsthesias; general faradization or static electricity, or muscle massage and resisted movements are said to do good where there is great and constant feeling of fatigue and muscular faiblesse. Last, but not least, these persons must have occupation and do suitable work without over-exertion and fatigue, but should also have frequent change of scene, travel, and the like, until considerable improvement is accomplished. As to relative recovery in neurasthenia from masturbation, provided the habit is promptly discontinued, the prognosis is good, with the exception of certain extreme cases mentioned above. Cases are met with where the desire is stronger than the power to resist, and the patients again and again relapse into the baneful habit. What is best to be done then? We may try to stop it by hypnotic suggestion. In his lucid and comprehensive book on the practice of hypnotic suggestion, by George C. Kingsbury, of Dublin, a successful case is mentioned by the author; I have tried it after Liébault's method with success in two cases. Now, when such unfortunates tell us that they have ceased to indulge after going down on their knees and uttering a fervent prayer to the Almighty to help them, and give them strength to withstand the temptation, and have risen with the firm resolution not to, and a consciousness that they will not do so again, and then really have not relapsed, they have probably done nothing else but cured themselves by auto suggestion.

Next in the order of frequency I should like to put cerebral and cerebro-spinal neurasthenia brought on by excessive sexual intercourse, and by coitus reservatus, *i.e.*, withdrawal before concluding the act. In some of these cases cerebral, in others spinal symptoms will predominate according to the individuality and occupation of the patient, and, aside of the measure of over-indulgence will be the more severe the more the patient's occupation and mode of life will act as additional factors in exhausting his nervous strength. "*Cessanta causa cessat effectus*" is particularly true here, the prognosis generally good, even as to perfect recovery, and the bromides, suitable hydriatric procedures, and the urethral sound will be all that is required. In the beginning of treatment I have found it of great service in the severer class of cases to insist on temporary conjugal separation, in order to allay the troublesome cerebral irritation.

Less frequent but more serious are the grave forms of neurasthesia by severe and protracted mental strain, associated with great responsibility and frequent anxieties, particularly when considerable physical or sexual demands have had to be satisfied also. We meet these in the large commercial centres among business as well as professional men more than anywhere else. It is here we often find greatly diminished tendon and cutaneous reflexes, very great muscular feebleness and feeling of fatigue after slight efforts, flatulent dyspepsia, tendency to diarrhœa, feeble heart's action with subnormal morning temperature, cutaneous affections in the form of eczema and the like; which symptoms show that the functional activity of the ganglionic cells has been greatly reduced by deficient nutrition or some derangement of their construction and physiological life which may be readjusted in the course of months or years, but may also go on to irremediable degeneration and leave the patient a chronic invalid. What has come under my treatment of cases of this type was already chronic when first seen by me. I am conscious of having done my best by a combination of our remedies to help my patients to regain health and vigor, but I cannot remember to have really cured one. Here again, after eliminating the presence of organic disease, we have a right to try hypnotic treatment. The author mentioned above, Dr. Kingsbury, in his "Casuistics," states the following important case:

"M. T——, aged forty-six, a very successful American merchant, had, owing to overwork, become thoroughly out of health, sleepless, irritable, anxious, depressed, easily startled, restless, and physically weak; he could only read for about half an hour at a time, and then became confused and suffered from pain in the head and spine. He expressed himself as thoroughly 'tired of life.' The last two years he had spent in travelling all over Europe in search of health, and had tried every form of treatment, including hydropathy, electricity, massage, and even suspension. He had lost all hope of being cured, and, though he had no faith in hypnotism, had determined to try it, so that he could not be reproached with having neglected anything.

"In all he had six sittings, on six consecutive days; and at the end of this time he was sleeping, walking, and eating well, and felt able to resume his work. He could not, however, believe that so marked an improvement would last, and fearing a relapse he remained under observation a month. He then stated that not only had he kept well, but he had continued to improve, and was about to set sail for America, 'feeling better than he had ever remembered to have been in his life.'"

Other observers claim to have had noteworthy successes with hypnotic suggestion, and in a recent correspondence with Professor Erb, upon a particularly severe case of chronic neurasthenia gravis from mental and physical overwork, he also advises that it be given a fair trial. I regret that my experiments with it in this particular case had to be interrupted when scarcely begun and cannot be reported therefore until later. Hypnosis should also be eminently useful in traumatic neuroses, inasmuch as in some cases terror has probably as much to do with producing the often fearful prostration and nervous asthenia as concussion; and hypnotic suggestion might prove of great value in removing its baneful influence upon the ganglionic centres. A few cases of neurasthenia, two of them rather severe, have been seen by me in syphilitic persons, after too prolonged inunctions with mercurial ointment, and some, again, due to syphilis

alone. The prognosis is not unfavorable as to early recovery, unless the underlying disease complicates matters. It will probably interest those of you who may not have had occasion to watch many of those people who are in the habit of dosing themselves regularly with Carlsbad salts for the purpose of keeping their bowels regular, that relatively small doses of sulphate of soda, not more than is contained in two drachms of Carlsbad salts, taken daily for some six weeks or longer, will be apt to produce pretty profound symptoms of neurasthenia in persons who are not robust by nature. Since my attention has been drawn to this peculiar action of sulphate of soda, in a case where I could eliminate every other cause, I have read of two similar cases of the kind reported by German observers. I have no reason to believe that the neurasthenic trouble in my case was due to diarrhœa, for the patient in question was too careful to take more than was just requisite to move his bowels. Aside from gastro-intestinal dyspepsia, and subsequent deficient nutrition of blood and nerves and muscles, it is not unlikely that the drug may have some directly poisonous effect upon the nervous system. With reference to an early cure of such cases, I can only say that it took my patient nearly a year to get well again. So far, then, experience has shown that neurasthenia is generally manageable, but not directly curable, and that, though it can be readily understood why a physician will prefer to apply at the outset the mode of treatment which he has practised most and is thoroughly conversant with, he can rarely hope to effect a cure by a single remedy, but will be better able to help his patient toward recovery by a wise combination of means and rules. We also know of chronic cases to have made a final recovery after many years' duration without further special treatment, and, therefore, it may be reasonable to expect that, by further and more extensive trials of hypnotic suggestion, and other means similarly direct in their action upon the central nervous system, we may succeed in relieving the state of functional derangement and hyperæsthetic weakness, better and faster than we have done.

25 West Forty Sixth Street.

OUR SCHOOL BUILDINGS, THEIR CONSTRUCTION, HEATING, VENTILATION, SCHOOL HYGIENE, PHYSICAL CULTURE, ETC.

By VALENTINE BROWNE, M.D.,

HEALTH OFFICER OF YONKERS, N. Y.; CONSULTING PHYSICIAN TO ST. JOSEPH'S HOSPITAL, ETC.

The holidays are past and the pupils of the various schools are once more required to resume their studies and thus prepare themselves for the many and varied occupations they will be called upon to pursue in the near future. In view of this fact may we not be permitted to ask those to whom we confide the education of our children a few pertinent questions in relation to the school-buildings, the class rooms, the mode of heating, ventilating, and air space, etc. ?

1st. Have you the necessary number of school-buildings for the reception and proper care of our children ?

2d. Are your teachers well qualified, from their home and school training and experience, to teach our children ?

3d. Have you well-appointed gymnasiums in connection with your schools ?

These are important questions, and every one of them should be answered in a satisfactory manner. Some of our school houses are manifestly unfit for use in these respects and should be relegated to the ranks of long past and superannuated curiosities.

What a School-building Should be.—Some few years ago the Board of Education of New York City appointed a committee with power to award a valuable prize for the best plan of a school building. After carefully examining several plans, the one selected embraced the following general conditions :

1st. At least two sides of the building should be freely exposed to light and air, for which purpose it should not be less than sixty feet distant from any opposite building.

2d. Not more than three of the floors spould be occupied for class rooms.

3d. In each class-room not less than fifteen square feet of floor space should be allotted to each pupil.

4th. In each class-room the window space should not be less than one fourth the floor space, and the desk most remote from the window should not be more than one and one-half time the height of the top of the window from the floor.

5th. The height of a class-room should never exceed fourteen feet.

6th. The provision for ventilation should be such as to provide for each person in a class-room not less than thirty cubic feet of fresh air per minute, which amount must be introduced and thoroughly distributed without creating unpleasant draughts or causing any two parts of the room to differ in temperature more than two degrees Fahrenheit, or the maximum temperature to exceed seventy degrees Fahrenheit.

7th. Heating the fresh air should be effected either by hot water or by low-pressure steam.

8th. The fresh air should be introduced near the windows; the foul air should be removed by flues in the opposite wall.

9th. Water-closet accommodations for the pupils should be provided on each floor.

10th. The building should not occupy more than half the lot.

Most of these recommendations are excellent, but in our opinion there are some very important features omitted, such, for example, as the location of the building in its relation to dampness and troublesome noises, the formation of class-rooms and corridors, the location of drain-pipes, water-closets, and other seemingly insignificant yet important details.

The school-building should, in addition to complying with the above recommendations, be located, if possible, on a dry, porous soil, on a knoll or other elevation, away from noisy public thoroughfares and distant from shade-trees, so as to permit free access of sunlight into every class room, and ample play-ground for the children. In case the above-named condition cannot be procured and a school-building must be placed on a moist soil, then the following suggestions should be adopted :

1st. The location of the building should be thoroughly drained by constructing a ditch outside of, and lower than, the foundation-wall, and then filling it in with loose stone to a depth of from twelve to eighteen inches.

2d. One or two similar drains should be made in the cellar and conveyed to a safe place to discharge. The cellar floor should be made water-proof by not less than six inches of well rammed concrete, or by asphalt, as recommended by Colonel Waring.

3d. The foundation-wall should be protected by a coating of asphalt, and a like coating or layer should be placed in the wall just above the ground to prevent dampness from ascending, and a hollow place should be left in the wall between the outer and inner layers of brick or stone so as to admit air and prevent moisture, and for the same reason the plaster should not be placed directly on the wall, but the wall should first be furred, lathed, and then plastered.

4th. The cellar floor should not be more than three feet below the surface of the ground, and the ceiling of the cellar or basement should be at least ten feet high, and it should be thoroughly lighted and ventilated, and should not contain a single water-closet, but should be kept scrupulously clean at all times.

5th. Cesspools and privy-vaults when used (in the absence of sewers) should never be located at a less distance than seventy five feet from the school-building.

6th. The class-rooms should be, in addition to the conditions before referred to, separated by a corridor not less than ten feet wide and extending from front to rear of the building, and the school house itself should always

front either north or south, so as to have the class-room windows on one side face the east and on the other side face to the west, thus securing sunlight in every room.

7th. The building should not be more than three stories high (except in large, densely populated cities), the two lower floors to be used for class rooms and the top floor for water-closets and a gymnasium.

Drainage of Waste Material.—The system of conveying sewage from the school-house is one of the most important features in connection with school hygiene, and demands the utmost precaution at the hands of the authorities. Water-closets should never be placed in the cellar or basement of a school building, because experience has shown and proved that it is utterly impossible to keep them in anything approaching a sanitary condition. Every person acquainted with the law of the diffusion of gases will at once admit that the natural tendency of them is to ascend, and that this upward tendency is very much enhanced by the warm air on the floors above creating an upward current, carrying with it the offensive and dangerous odors from those water closets. It requires no scientific demonstration to show with what facility those foul odors permeate every room in the building, because you have a practical illustration of the fact from your own kitchen during cooking hours. If you have any lingering doubt on this point just ask the cook to place some onions in the frying-pan over the kitchen-fire, or some carbolic acid, or oil of peppermint in hot water, with directions to stir a little, and then elevate yourself to the top floor, and you will be surprised to find the odors of those rosebuds there before you. If now you transfer the kitchen to the top floor, and tell the cook to repeat the dose, while you descend to the basement, you will not, you cannot, detect the invigorating perfume from those articles; hence the necessity of thorough cleanliness in cellars, and hence the absurdity and danger of placing those ill smelling closets in the basement. The most appropriate and the most sanitary location for these closets is on the top floor of the house, and when proper precautions are observed in the arrangement of them, there cannot be the slightest objection to their presence there. These closets should be located at one end of the top floor, separated by a solid stone wall from the rest of the floor or gymnasium. They should be reached by means of an iron staircase, constructed on the outside of the building, with appropriate landings and connections for each floor. The staircase should be partly enclosed, somewhat after the manner of the elevated railroad structures, to provide against inclement weather. The drain pipes should be of the best material, and should be thoroughly exposed along their whole course within the building. They should be located in a well lighted portion of the building, so as to enable the janitor to detect at once the slightest leak or other defective feature in them. Again, the danger of taking cold by exposure to cold air and draughts on the way to and from water-closets placed outside of the school-building, would be reduced to a minimum.

Some of our school boards congratulate themselves on providing water closets or vaults some twenty or twenty-five feet away from the school-building without any enclosed passage-way leading to them, thus, they say, excluding from class-rooms all danger from sewer-gas. I know many such cases, but there is one in particular where the school board for several years maintained two huge vaults, one on either side of the school-building, and hardly thirty-five feet distant, provided with no ventilation except what escaped through some lattice-work over the centre of the enclosure, extending not more than fifteen feet from the surface of the ground. It mattered little which way the wind blew, it was sure to convey the decomposed, sickening air from one or both of these vaults into the school house. Some improvement has been lately accomplished by converting these vaults into water-closets, but the location and ventilation remain the same as formerly.

Would it not be inconvenient for children to climb two flights of stairs to reach the top floor? Not at all. It would only reverse the condition of climbing. In case the closets were on the ground floor, or outside of the building, they would first come down and then climb the stairs, instead of first climbing and then descending. Besides, when stairs are properly constructed, the labor of ascending them will be a source of physical exercise, which the pupils should have.

While speaking on the subject of stairs in school-houses, perhaps a few remarks on their general construction may not be considered a digression. Stairs in a school-building should never be placed in dark, out-of-the-way corners, but should be located one at either end of the corridors, and facing the door and windows so as to be thoroughly lighted by the glass swinging vestibule-door and windows. Stairways should be fire-proof and provided with at least one landing half-way up, but should never be winding or spiral-shaped. "The tread should be wide and easy to climb. That portion of the corridors between the door and staircases could be utilized for clothes-closets, and these closets should be so constructed as to admit plenty of fresh air to the wraps." They should have ventilating tubes leading from the top of the same to a properly constructed ventilating flue provided in the wall of the corridors, so as to prevent possible contagious vapors ascending to the class rooms from the wraps of the children not over-cautious in the care of their garments. Measles, scarlet fever, and diphtheria are often communicated by means of these wraps when not properly aired and ventilated. Class-rooms, as before stated, should be large, well ventilated, and in addition to the windows opening directly to the outer air, should also have not less than two windows, each say two and a half feet by three feet, opening into the corridor near the ceiling, and arranged so as to open and close at will, thus enabling the janitor to thoroughly flush the rooms and corridors during recess. By lowering the large windows and opening the small windows on both sides of the corridors a rapid current is at once established which will effectually remove all impure air and foul organic matter usually found near, and often adhering to the upper portions of the walls and ceiling. In no other way, and by no known system of ventilating shafts can these impurities be so thoroughly removed from the class-room ceiling.

Class rooms should be large enough to allow each pupil three hundred cubic feet of air space. This would require for a class of fifty pupils a room twenty-five feet wide, fifty feet long, and twelve feet high, or fifteen square feet of floor space for each scholar. How many school boards furnish this amount of space? We pause for a reply.

Desks and Seats.—Desks and seats in class-rooms should be placed so as to admit light on the left side of the pupil, and the most remote desk should not be more than twenty feet from the window on the left, and each scholar should have the sole use of one desk. There seems to be some difference of opinion as to the size, shape, and position of desks and seats in the class-room. Some think that a desk should be nearly flat, while others say it should be tilted "In my opinion it should be nearly flat for writing on, and its edge should project over the front of the seat or chair, and the height should be so arranged as to allow the arms to slide over it without lifting the shoulders." While reading, however, the lid should be tilted so as to form a convenient book-rest. Desks embracing these qualifications can now be procured at very reasonable terms

Perhaps there is more difficulty in supplying the ideal seat or chair to suit the various notions not only of the pupils but also of the teachers, or rather the school authorities, than in the selection of any other article of school furniture. Some believe that it is necessary to support only the lower third of the back; others declare in favor of a chair with a curved back; still others say that support is needed for half the back; yet others would allow only a narrow strip for the support of the

spine, while quite a number would do away with chair backs altogether.

Between these conflicting opinions it seems hard to decide what sort of a chair to select. In my judgment the chair having a straight, upright back, somewhat concave from side to side, is the most appropriate for general school use. This kind of chair, I think, will be found the most convenient for writing, reading, drawing, copying, ciphering, etc.; in fact, for all work requiring an upright position.

Seats should not be placed too far from desks, but should be so placed as to allow the edge of the desk to overlap the front portion of the chairs. Desks and chairs thus shaped and placed will enable the teacher to correct many faulty positions so often assumed by school-children while occupied with their studies, and will prevent many of the deformities usually observed in young pupils.

Teachers should devote more attention to correcting the abnormal positions of pupils than they are in the habit of doing. It is a fact that neglect of seemingly insignificant details has been the cause of inflicting untold injury on numberless school-children. Any close observer cannot fail to notice the excessive number of boys and girls compelled to wear eye-glasses on account of defective vision caused by imperfectly lighted class rooms and the position of black-boards on the walls, at which they are compelled to gaze so much during school-hours. Many of the deformities so often seen among school-children are due to the unnatural positions which they are allowed, or perhaps compelled, to assume during school years, such, for example, as curvature of the spine, round shoulders, contracted chest, etc.—deformities which unquestionably predispose them to fatal diseases and premature decay.

The spread-eagle-like position, so commonly indulged in by the pupil when at work, without any remonstrance from the teacher, is so manifestly detrimental to the physical development of the pupil as to demand thorough reform in this important department of school work. If teachers were a little more exact in correcting these abnormal positions in the pupils, by compelling them to maintain an upright attitude while engaged in school duties, they would not only prevent many of the deformities referred to, but would also confer lasting benefits on future generations.

Class-rooms should never be separated by glass partitions or glass sliding-doors, for the reason that it has been thoroughly demonstrated that such an ancient makeshift contrivance does not improve the character of light in the rooms remote from the windows, while it diminishes the light in the room next the window in a very perceptible manner. "The glass in the partition reflects a part of the light and throws it back and out of the window." Glass also reflects light and allows part to pass through and out by the window on the opposite side, while the noise, at times unavoidable, in one class-room, becomes a nuisance to teacher and pupils in the next room, and *vice versa*.

Class-room windows should extend from, say three feet above the floor, to a point within six inches of the ceiling, so as to afford light to the students remote from them, and for the further purpose of thoroughly flushing the class-rooms at least three times a day during school-hours. These windows, however, should never be open either from bottom or top when the temperature outside of the building is more than ten degress lower than that in the class-room, on account of the marked tendency of some children to take cold. Yet when pupils and teachers alike experience that disagreeable condition of almost suffocation from hot, impure air, we must acknowledge that it is hard to resist the natural impulse which seems to prompt them to open the windows. When such conditions unfortunately occur, and fresh cold air must be had, the children should stand up and practise some rapid movements of the whole body, as required in many of our schools. Even with these athletic motions a sudden rush of cold air on the pupils has too often caused severe colds to be contracted by delicate children, and hence the necessity of vacating the class-rooms while they are being aired.

Country School-houses.—With these remarks in relation to large school-buildings in cities, we will now pass to an examination of school houses in the outlying districts or country towns where a large building is not required. It has been, and I believe is still, the custom to run up a one-story shanty, about twenty by fifty feet, anywhere, regardless of the nature of the soil, cellar, or other important details.

The interior is sometimes decorated with a vestibule, and usually one class-room, in which imaginary lines are drawn to separate the various grades into which the pupils must necessarily be divided. The ceiling of this lofty institution of learning may be anywhere from ten to twenty feet high, and the building is provided with windows on every side, including also each end, and these windows are expected to furnish light and ventilation at one and the same time.

The class-room is large enough to accommodate forty persons, but in cases of emergency more than double this number may be admitted. The building or class-room must be warmed by a huge stove, placed usually in the centre of the room, where, in cold weather, it is expected to make itself red hot, regardless of the poison it evolves. The black board is placed between windows, and the children are required to strain their eyes in looking at it during their exercises, thus inflicting injury to the eyesight which in many cases can never be repaired.

School authorities seem to regard isolated or outlying district-schools as matters of little consequence, either as to their location, construction, heating, or ventilation, and as a natural sequence, those buildings are generally badly located, imperfectly constructed, too much lighted, indifferently heated, and completely devoid of ventilation, save only that furnished through the open doors and windows.

Why is this? Why make any distinction? The children in country districts are just as much entitled to properly constructed school-houses as those in the cities. The State or Church should not permit any such distinction. Farmers are taxed for maintaining the school as well as the business man or mechanic, and are justly entitled to equal school accommodation for their children.

Do they get it? A visit to any one of those barns called district schools will answer in the negative. Instead of erecting a shanty twenty-five by fifty feet, build a two-story house, any size from thirty-five to fifty feet wide by fifty to seventy five long, as may be required, and let the two or more class rooms be separated by a corridor, as recommended elsewhere, extending the whole length of the building. The first floor will offer ample class-room, clothes'-room, etc., while the second floor can be used for a gymnasium and play-room in wet weather.

In places where the number of school-children is limited to, say thirty or forty in a district, a one-story building may suffice. In that case the school-house should extend from east to west, and be provided with a corridor on the north side of the house, the class-room windows looking to the south only. By this arrangement the black-board could be placed at the west end of the room, the pupils facing it, while the teacher's desk would be, of course, at or near the black-board, thus allowing light to enter above and to the left of the children. In case of too much sunlight through these south windows, light-colored shades may be used to moderate and equalize the same at pleasure.

Drinking-water for school-children should claim the most earnest attention of school boards. In districts where city water is not available, well or cistern water is that usually resorted to. Well-water may be, and generally is, in country districts, safe to drink; but when, as sometimes happens, the well is located within a less distance than fifty feet from a vault or cesspool, the water in such well should not be used for drinking purposes, and a vault or cesspool placed at a less distance than forty

feet from the school-house should have a ventilating pipe taken from the said vault or cesspool and conveyed to the outer wall of the school-house, and then extended to the highest point of the roof By this pipe most, if not all, of the offensive odors from those foul receptacles may be removed beyond the roof of the building, instead of being drawn into the class-rooms, either through the cold air conduit or through the windows, as frequently happens. Each of these latter school-buildings, no matter how small it may be, should have a well lighted and clean cellar in which a good hot air furnace should be located.

Gymnasium.—Every school and educational institution ought to have a well-equipped gymnasium attached to it, so as to enable the pupils to cultivate and develop the physical as well as the mental faculties. This important branch of education has been too much neglected in our public and parochial schools, and, indeed, in many private schools, academies, and colleges as well. Of late years, however, not a few in charge of these institutions are waking up to a realization of the fact that physical education must soon become an important feature in the curriculum of the institutions under their care, and have accordingly provided gymnasiums for their students. Let the good work go on until every school, high and low, male and female, public and private, shall furnish its pupils with a systematic mode of acquiring physical culture, and thus enable them to blend and harmonize in a happy manner those two divisions of education, without which there cannot be a finished, healthy termination to school-work.

But, say many of our school-managers, these gymnasiums are very expensive and we cannot afford this luxury. Do not allow the expense to deter you from establishing what is a necessity, not a luxury. Better reduce your expenses in some other direction than graduate a mental Shakespeare enclosed in a physical Pope.

Physical training, like mental cramming, can be abused by over-exertion. Excesses, of course, must be avoided. The kind of exercise and the time devoted to it must be of a character suited to the particular student, for it is evident to even a casual observer that the amount and kind of physical exercise which may with safety be indulged in by one, may prove too fatiguing to another. For example, would it not be absurd to require the same amount of physical exercise from a weak, debilitated-looking boy of, say twelve years, as that required from a healthy, robust-looking youth of the same age?

Physical exercise for school-children must be selected with great care and subject to the advice of the family physician, and under the eye of an intelligent instructor in gymnastics. Otherwise, instead of developing and strengthening the bones and muscles of the pupils, it may cause deformities of certain parts of the body, atrophy of one set of muscles and abnormal development of another. Hence the necessity for a competent instructor in every gymnasium.

In our day and time physical culture is gradually and effectually gaining in every civilized country. Intelligent people begin to see and understand that their intellectual faculties cannot attain that high degree of perfection so earnestly desired, unless they are intrenched or fortified by a sound physical frame, and that this condition cannot be achieved without physical exercise. "The body cannot become a perfectly working machine without culture, any more than the mind can become intellectually perfect without education." "Let me have a sound mind in a healthy body," says Juvenal, in his prayer to the gods. States and nations should show as much zeal for the cultivation and education of the physical as they do for the mental faculties of the people, because it is now a recognized fact that in those countries, ancient and modern, where physical culture formed an important feature in the education of the people, the highest type of the intellectual faculties was usually found.

"The poetry of Homer grew and lived on the same soil that produced Leonidas and his veterans." In ancient Greece physical culture was from the days of Homer made an important part of the school curriculum. The education of the Greek youth was divided into three parts—grammar, music, and gymnastics, to which painting or drawing was added by Aristotle. In the city of Athens gymnastic exercises occupied as much time as all the other branches or divisions combined, and were continued long after mental education terminated. There was not a Greek town without its gymnasium, and the large cities had several. History tells us that just before the time of Hippocrates gymnastics were made a part of medical study, to counteract the effects of indolence and luxurious feeding.

The wisdom which prompted the ancient Greek and Roman to introduce and perpetuate manly sports and games was abundantly manifested in the magnificent proportions of the Athenian, the Spartan, and the Roman. You cannot name a single historical person in the annals of those ancient countries that was not a trained athlete. Homer, Achilles, Patroclus, Plato, Aristotle, Socrates, Demosthenes, Hippocrates, and a host of others renowned in ancient Greek history, were skilled in gymnastic exercises, and the fame of Athens as an educational centre attracted pupils from all parts of the civilized world.

The Romans, desiring to equal if not to excel their Grecian neighbors, quickly adopted and utilized those invigorating games that contributed so much to render Greece almost invincible for so many ages, constructed the most magnificent and costly gymnasiums and bathing-houses combined, for the cultivation of the physical faculties of her people. But with the decline and fall of Greece and Rome came neglect of gymnastic exercise, loss of physical strength, and general depravity.

During the middle ages but little, if any, attention was paid to physical culture, and it was not until 1776 that any effort was made to revive the almost forgotten games and sports of ancient times, when Basedow united once more mental with physical exercise. From this small beginning the practice slowly extended, until in the latter part of the eighteenth century gymnasiums were extensively introduced into Prussian schools. In the year 1810 Jahn instituted the well-known organization called the turnverein, a body of athletes which materially enabled Prussia to expel the French from her soil more than any during the present century.

The revival of gymnastic exercises in Germany soon spread over most European countries, but not until 1848 did the contagion reach our shores, when the German exiles laid the foundation of the turnverein in New York, where it has flourished, and from which it has extended to almost every city in the United States. During the past ten years many colleges and some high schools have introduced gymnasiums; but as yet very few, if any, of the primary schools are furnished with these desirable institutions.

The kind of exercise best calculated to improve the physical condition of the average school-boy or girl is a matter which should receive special attention from the authorities. The physical exercise for the young pupil which affords the greatest amount of pleasure to the particular student is the kind that should be adopted. In recommending that exercise most pleasing to the individual do not understand or imagine that we are in favor of any athletic games having a vicious or demoralizing tendency. Not at all. The various sports and games so highly enjoyed by boys could hardly be recommended for girls. The exciting games of baseball, football, hand-ball, jumping, bicycle riding, climbing, boxing, bowling, running after a fire-engine, military drill, and such like sports and pastimes, so exciting and attractive to boys would hardly be the proper exercise for girls, unless they donned the Bloomer costume on such occasions. Even then we should still object to those violent forms of exercise for the fair sex on account of their exhausting character. Many of these games are being indulged in to excess by persons physically unable to stand the fatigue consequent upon such exercise.

Moderation in physical exercise is as necessary as in

any occupation and should be indulged in accordingly. It is much to be regretted that most of those violent and fatiguing games are being resorted to during the warmest part of the day and year when repose is so necessary. We have often been surprised at the wonderful endurance of young men who will play baseball under the burning rays of a midsummer sun when the mercury registers one hundred and thirty degrees or more in the sun.

Do not understand us as being opposed to physical exercise for girls, because we know that exercise is just as requisite for girls as for their brothers, but somewhat different in character. They have croquet, lawn tennis, dancing, walking, skating, horseback riding, running, and certain kinds of indoor exercise in the gymnasium, all of which tend to develop bone and muscle and thus enable them to resist disease and enjoy long life and happiness.

There is no exercise more pleasing to the average schoolboy or girl than a wild romp and unrestrained screaming for ten or fifteen minutes in the school-yard during recess. Such complete relaxation in the open air from the rigid rules of school discipline seems to infuse new life into the pupils, by expanding or inflating their lungs with fresh air, while at the same time the foul air of the class-room is completely expelled. This important effect cannot be obtained by the system now in vogue in most, if not all, of the common, and many parochial schools, of opening the windows for a few minutes while the pupils stand and stamp. All that can be said in favor of this new system of prancing is that it is a little better than no air or exercise at all. Why? First. If the desks and chairs are properly placed there is no room for the pupils to stand erect, and they are forced to assume a position not of ease but of discomfort and contortion, and consequently are not at liberty to move the hands and feet as they would wish to or as they could in the playground, and while in this awkward position the windows are thrown open, the cold air thus unduly cools the class-room and causes delicate children to take cold.

For the foregoing and other reasons we think that school-managers are wrong in abolishing the old time recess of fifteen minutes in the middle of each school session. No sound reason has been advanced in favor of the change except, perhaps, the coeducation of the sexes, which we suppose forbids or precludes the emptying of all the class-rooms at the same time, the object being not only to afford fresh air and exercise for the pupils, but also thoroughly to flush all the class-rooms with fresh air. Whatever cause or combination of causes worked the change, whether it was coeducation or some other absurd rule that prohibited this old and excellent method for furnishing air and exercise for the children, it is much to be regretted that the change ever took place in our schools.

Military drill has lately become an important feature in many schools and colleges, and it is demanding and receiving much attention from interested parties. While it is admitted that this kind of exercise tends to correct certain abnormal positions in the rapidly growing boy, we cannot recommend its general adoption for boys under eighteen years of age, on account of the fatigue which it inflicts on the pupil, unless very judiciously practised under the eye of a competent instructor.

In short, any long-continued exercise, having a direct tendency to fatigue, or unduly exhaust the pupil, should be avoided by the young athlete. Too violent exercise not only does not develop the muscles, but frequently retards their growth, and leaves the boy puny and delicate. "During the active growth and development of the body the bones are soft and spongy, and contain more blood, relatively, than those of the adult, and consequently are more liable to yield to violent exercise, thus causing inflammation and deformed conditions of those parts to take place." The vital organs, as well as the bones and muscles, are in process of rapid development, and are much affected by too violent exercise, and, as a result, we have enlargement of the heart, rupture of blood-vessels, and various other affections of those organs.

Bicycle riding, by causing a forward inclination of the upper portion of the body, is not recommended for the immature youth, on account of creating a decided tendency to form round shoulders and a contracted chest. I regret to express this opinion of the bicycle, more especially on account of the fact that some of the gentle sex seem determined to indulge in this masculine sport. While we are delighted to see young ladies indulge in out-door sport and games, still we cannot approve of certain kinds of those exercises before mentioned. Those occupations are, we think, too violent for the usually frail constitution of girls, and in no way tend to a vigorous development of their muscular system, but, on the contrary, they have been the primary cause of certain ills requiring the aid of the physician.

In thus restricting our girls in the choice of athletic sports and games we differ materially from our ancient Grecian friends, who required their daughters to publicly exhibit their gymnastic proficiency before contracting marriage. But as there were no bicycles for the Spartan girl to ride in those days, we cannot dogmatically say what action their fathers would have taken in the premises. Certain it is, however, that the Author of our being did not deem it necessary to endow the female portion of mankind with the same rugged bone and muscle which characterizes the male element of creation.

Overcrowding Class-rooms.—In another part of this article we stated that in the opinion of the best sanitary authorities not less than fifteen square feet of floor room should be allowed to each pupil, the ceiling being at least twelve feet high. In the higher grades some of our class rooms afford a little more than half this amount to each scholar, simply because the attendance in those grades is small as compared with the lower grades, and not on account of the sanitary demands of the children. As we descend from a higher to a lower grade we find the class rooms more and more packed, until, on reaching the lower grades of the primary department, it is not unusual to find children so packed in these imperfectly ventilated rooms as to render the air absolutely detrimental to the health of the inmates.

Picture to yourself a room twenty five by forty feet with an average attendance of eighty persons, seated on hard benches or chairs, with the feet of the smaller ones lifted off the floor, no support to the back and no desk in front of them, closely packed together and forced to inhale poisoned air for two or three hours at a time. In this class-room there are three windows and one door, the only channels through which fresh air is admitted and foul air expelled. As you enter this apartment from the open air you at once detect something wrong in the character of the atmosphere. You notice a disagreeable, sickening odor, or combination of odors, which at first prompts you to retrace your steps. You observe the children seated as before stated, some with pale, sickly expressions, others with flushed faces, all listless and restive. If you remain in this room you imagine that the disagreeable odors are no longer present, your sense of smell for this particular air is for the time completely effaced, and you soon begin to feel the evil effects of the poison that is being conveyed to your lungs, your heart, and your brain. Carbonic acid that should have been purified or removed from the room remains to be again and again inhaled, thus slowly but surely poisoning the system and destroying the vitality. Such is the general character of the air those children are compelled, by a cruel, iron-clad law, to inhale for hours in a so called school room. Children who were bright with rosy cheeks and as merry as the lambs of the field are, at the tender age of four or five years, shut up in those polluted apartments, and deprived of that which is most essential to the health and happiness of the individual, fresh air and exercise, and plenty of it.

Such school rooms serve another very objectionable purpose in a superlative degree, and that is in the spread

and propagation of such contagious diseases as scarlatina, measles, whooping-cough and diphtheria. The mode of conveying these contagious and infectious diseases through the agency of such packing is evident and may be summed up thus: A mild case of either of the diseases above named occurs at the residence of one of the children, so mild indeed that its nature is not recognized by the parents or others in the house. The little patient plays about with nearly his usual vitality, mixing with his accustomed playmates, or perhaps, as often happens, he continues to attend school for some time before the nature of his complaint is discovered, or until the disease has been communicated to other members of his class. Or the little student may be perfectly well and free from the actual disease himself, but his garments may be saturated with the fatal germs of diphtheria, contracted from a member of the family at home, or even from a neighbor's child. In this way whole schools have been exposed to the danger of infectious and contagious diseases despite the efforts of the most vigilant health authorities, and from this fertile source of contagion whole communities have been made to suffer irreparable losses.

The tyrannical law which compels children at the tender age of five years to attend such schools is as unjust as it is unconstitutional, and ought to be disregarded, because it is an unwarranted attempt to interfere with the guaranteed rights of the citizen to force him to educate or train the intellect of the child at the expense of, and to the absolute detriment of, that vastly more important element of his being, namely, physical development.

Standard authorities tell us that each pupil should have not less than fifteen square feet of floor space, or from two hundred and fifty to three hundred cubic feet of air. Now let us consider the condition in a class-room which I have visited lately and see how much air space is furnished each child. This room is fifty by thirty feet, and an average of seven feet high, and seats one hundred and fifty children. Light and ventilation are furnished by six windows and two doors, and the room is heated by direct steam radiation. In other words each scholar has the liberal supply of seventy cubic feet of air space, or about one-fifth the required amount. How, in the name of humanity, can a child learn his lessons in a room like this? Is it any wonder to find them inattentive, listless, and stupid when subject to such deleterious influences?

Observe these children at the commencement of the school term and you will notice how fresh and animated they are, with bright, sparkling eyes and rosy cheeks, full of life and vigor. But a change takes place before the end of the school year which completely alters or changes the physical condition of the pupil. The fresh, buoyant, animated condition is gone, the rosy cheeks have been replaced by a pale, dull expression of countenance; the pupil is languid and longs for the termination of his imprisonment; nervous headache, neuralgia and many other complaints torment him, and frequently the vitality is so reduced as to expose him to many contagious diseases and not infrequently to one or more of the lingering complaints that so often terminate in premature death, and thus forever close the perhaps bright prospects of the pupil of an overcrowded and imperfectly ventilated class-room.

The physical and mental outrage so perpetrated on children compelled to attend schools of this character should not be tolerated in a civilized community. It is bad enough to confine children for several hours in a room having the requisite amount of air space, but when they are packed like sardines in a box and forced to inhale over and over the poisonous exhalations from the lungs it becomes positively criminal. Why, we ask again, should such conditions be tolerated in a civilized country—a country which claims the right to educate our children in violation of constitutional law? Why should it disregard the just demands of our children? If the Government has the right to erect expensive school-buildings, and spend fabulous sums on teachers, principals, and superintendents, and foreign languages, has it not the same right to furnish room and air enough for the scholars?

If school authorities neglect to supply proper school accommodations what right have they to demand the attendance of our children? It has been truly said that "knowledge is power," but what use can a physical wreck make of the most complete education? Better allow our children to grow up in comparative ignorance than to subject them to physical ruin by shutting them up in a class room saturated with the germs of disease. Public schools, parochial schools, and even private schools, should look into this important matter before it is too late, because the time will come when education and sanitation must harmonize.

TYPHOID FEVER, ITS DE NOVO ORIGIN.

By HUBERT WORK, M.D.,

PUEBLO, COL.

A COLORADO farmer excavated a pit in which he wintered his potatoes, about two hundred sacks of which remained as refuse the following summer, exposed to the sun and rain until the latter part of July, when the irrigating canal overflowed, ran through the corral, and flooded the potato cellar. A dead cow was then turned in and the pit filled with dry earth.

On August 28th the house-wife complained of being ill, took to her bed September 2d, and subsequently developed typhoid fever of so grave a type that her life was despaired of.

September 4th, Fred, aged fourteen, was similarly attacked, and very soon gave evidence of being almost overcome by enteric fever. September 8th, a hired man took to his bed with the same disease.

Use of the well, which was located thirty feet from the potato-pit, was forbidden immediately after the nature of the first illness was determined, September 2d or 3d, and no new cases developed until September 25th; but within the seven days subsequent thereto the daughter, aged sixteen, hired man number two, two boys, aged six and nine respectively, and two young men from neighboring ranches—frequent callers upon the sick—were put to bed with typhoid fever, three of them on the same day; and twenty days later the remaining farm-hand fell ill with the same disease—none of these, however, being so prostrated from the beginning of their illness as were the two first attacked.

But two of the twelve persons known to have drunk water from this well escaped the fever—the farmer and the wife of a hired man, both of whom had suffered well-marked attacks of the disease some years previous.

Inquiry elicited the confession that water from the quarantined well had been used since September 18th, they believing that it had been purified by constant use for watering stock—some twenty head of horses and cattle—for more than two weeks.

As may readily be supposed, there was little assistance proffered by the neighbors to this family, but of those who did assist in their care none drank from the well and none contracted the fever.

Further interest attaches to these cases from the facts that the two first attacked, representing youth and middle age, developed the gravest form of the disease. Extreme tympanites, diarrhœa, persistent high temperature with slight morning remissions, somnolence, low delirium, exhausting abscesses and great emaciation—symptoms which rarely occur to such a marked degree in this disease at an altitude greater than four thousand feet, excepting that of hyperpyrexia. But one of those who contracted the disease after two weeks' use of the water for stock only, sank so low as did those first attacked, and he only after suffering a relapse, from which, however, he recovered, as did all the others.

The fever stadium varied from twenty eight days in the uncomplicated cases, to forty-two days in those who

suffered relapses, and there was no room for doubt in the diagnosis of any case.

The passages of those ill were invariably voided into a solution of chloride of lime, to be afterward buried; and the soiled linen was boiled in an antiseptic solution, so that the infection of the second series of cases by the stools of those first ill was not possible.

No typhoid fever had ever developed upon this ranch previous to this time, and no case of the disease had developed nearer than seventeen miles during the same year, previous to these. The discharges from these far distant patients could not have reached this infected ranch by either natural or artificial water-courses, should such a contingency be thought probable from so great a distance.

Sewerage of cities or towns was not discharged into the river supplying the canal nearer than sixty miles, and only five other cases developed near this canal during this year, although it supplied water to many hundreds of people. No other cases occurred in the families of the two young men who called on the sick and later were themselves attacked, although all were unprotected by previous attacks of the same disease.

It would seem reasonable to conclude that the decay of this vegetable matter, or the saturated barnyard manure, or both, had developed the specific toxic principle capable of producing typhoid fever in the unprotected, and that its access to the well was accomplished by seepage, favored by its situation and by the natural inclination of the soil strata, which is known to be from the location of the decomposing matter toward the well.

Granting these conclusions to be correct, it would appear that because those first attacked were more profoundly affected from the beginning of the disease to its termination than were those who contracted the malady after two weeks' use of the well-water had diluted the materies morbi, that the violence of the disease is in a great measure determined by the concentration of its exciting cause.

Thirty feet of sand, through which the water percolated before reaching the well, seems insufficient for the removal of the typhoid germs, and is further evidence that the earth has no power to purify water carrying this microorganism. Analysis of the water was not obtained, two attempts in that direction being frustrated by accidents in transportation.

Physicians who have sought for probable causes of enteric fever, occurring on the Colorado prairies, very soon become committed to the theory of its *de novo* origin.

Where settlers are separated by many miles, and often located long distances from running water or other known carriers of its exciting cause on the virgin prairie, it is impossible to cite as a cause pre-existing cases of the same disease. Isolated cases of this disease occurring under such circumstances are common, and from those which have come under my observation the following have been selected because of the definite knowledge of their histories.

One year after the settlement of a family upon the arid prairies, eighteen miles from water, a hemiplegic daughter, aged eighteen, contracted typhoid fever, from which she died in the fourth week. She had not left the house further than a few feet during the year previous. No one had visited the family and afterward developed the disease, nor did any other member of the family contract it. No other case of the disease had occurred nearer than fifteen miles, and not later than five months previous to her sickness.

G. G——, aged eight, contracted typhoid fever after eighteen months' residence on a newly located ranch, in every respect of similar environments with that mentioned above, except the distance from living water in this case being five miles, and the time elapsing since the patient had been from home being two months. In both families the water supply was taken from new wells, fifty feet deep.

The frequent occurrence of typhoid fever on the isolated cattle-ranches of Colorado materially strengthens the propositions from time to time advanced, that water polluted by the excreta of cattle furnishes the potent factors capable of producing and conveying its exciting cause. For many cases there are no other causes deserving of suspicion in this country, where annual autumnal droughts prevent decay of vegetable matter during the season to which typhoid fever restricts itself, and the miniature lakes of waste water and manure seen at the wells of these stock-ranches are too frequently associated with typhoid fever in the house, as to time at least, to be wholly ignored as a cause.

Although the above detailed histories do not prove anything new or old, yet to the writer, who had daily knowledge of the ranch on which the cases first described occurred, and of all those who resided thereon since it was unbroken prairie up to the outbreak of this endemic, and had ample opportunity to verify the facts in each case recited, it is evidence against the conclusions of many who have made for us investigations inquiring into the causes of enteric fever, an example of which is, to quote the language of James C. Wilson: "This microorganism, which is then the infecting principle of enteric fever, is invariably derived from a previous case."

419 Santa Fe Avenue.

IRRIGATION OF THE COLON IN INFANTS.

By J. H. HUDDLESTON, M.D.,

PHYSICIAN TO CHILDREN AT THE NEW YORK DISPENSARY AND ARTHUR BRAUNLICH.

Since the beginning of the diarrhœal season fifty children under two years of age have been treated at the New York Dispensary by irrigation of the colon and regulation of the diet without medicine. These fifty have not been picked cases, but on account of lack of time only a small proportion of those daily presenting themselves could be so treated. If a case at the second visit was found to need also stimulants, bismuth, or opium, it received that additional treatment. The majority, sixty-six per cent., were relieved by one irrigation, some were washed out twice, a few three times. A small proportion, twenty per cent., received additional treatment. One case was washed out, did not return, but died on the third day after being seen. Search has so far failed to reveal another death among those treated in this way.

Method.—The infant, bared of shoes, stockings, and diaper, is placed across the mother's lap face down, with the legs hanging by her side. Beneath the child's abdomen is a sheet of rubber cloth which is held snugly around its waist by the mother; the lower end of the cloth rests in a small tub placed beside the mother's chair. A two-quart fountain syringe filled with a salt solution of nearly normal strength (six per cent.) is hung about four feet above the baby. The water is at the temperature it flows from the faucet—*i.e.*, from 68° F. to 75° F. In the middle of the tube leading from the bag is a glass pipe which serves to show when the current is flowing freely. To the nozzle is attached a large soft rubber catheter (size No. 12). This is anointed with vaseline, passed up the baby's rectum and colon as far as it will go, and the entire contents of the bag allowed to flow through it. If the water tends to come out at the anus immediately, an attempt is made to stop this, by compressing the buttocks, and plugging the anus with a bandage rolled about the catheter. The catheter is then withdrawn, and the mother holds the baby for four or five minutes in a sitting position over the tub to let the retained water pass out. In passing the tube there is frequently some obstruction met near the upper end of the rectum, but if the tube is held there and the water allowed to flow, the obstruction usually disappears, and it is the rare exception not to be able to pass the catheter its whole length. In some few cases, however, the tube could be passed only a few inches, and would double up

and come out if pushed farther. The infant is placed on its face, as in that position its kicking interferes less with the passage of the catheter. A large receptacle for the wash water is needed, as the discharges are often shot out forcibly a considerable distance. The amount of water retained varies from a few ounces to the entire two quarts. When a quart or more is retained the child usually vomits the contents of the stomach, but in no case has it been evident that the water reached the stomach through the intestine. The water which comes away around the tube is usually clear, that which comes away later is generally stained yellow or green. Very little fecal matter is ever brought away. Some children scream all the time the catheter is held in place, others, screaming before, are quiet as soon as the water begins to flow, still others do not appear to notice the treatment.

Results.—In almost every case the subsequent effect has been quieting; the infant has often gone to sleep before leaving the dispensary and usually is asleep before reaching home. It is less thirsty for several hours, and, as a rule, is reported exceptionally quiet during the following night. If much water is retained the abdomen becomes tense, and in a few cases has felt cool to the touch. In two cases it was possible to mark out the transverse and descending colon by the sharply defined cold area felt on the abdominal wall. In two other cases there have been disturbing symptoms; in one there was apparently a chill, the child shook, became slightly cyanotic, and vomited; a few drops of aromatic spirits of ammonia and the warmth of a blanket caused the color to come back speedily; in the other, the infant became pale, felt cold, and showed a feeble pulse; the same treatment revived it promptly. In one case the mother reported that after the irrigation stools were accompanied by a prolapse of the rectum, whereas before there had been no such trouble. The effect in diminution of the number of stools depends largely on the character of the diarrhœa. In eighty per cent. there was some diminution; the few cases unaffected in this respect were bottle-fed babies in poor condition, and the illness was acute and of great severity. In cases of simple acute diarrhœa in babies in good condition a single irrigation with correction of the diet has usually been found sufficient for a cure; no case of cholera infantum has been treated by irrigation. In cases of chronic diarrhœa the number of stools was usually reduced to a half or third of the former number and the effect lasted twenty-four to thirty-six hours. If there was blood in the stools two or three irrigations were never found sufficient to cure, though benefit in the reduction of the number of stools and in the general condition of the patient was obtained in every case.

The Age of Maturity.—Statistics are said to show that young men do not, on the average, attain full physical maturity until they arrive at the age of twenty-eight years. Professor Scheiller, of Harvard, asserts, as the result of his observations, that young men do not attain to the full measure of their mental faculties before twenty-five years of age. A shrewd observer has said that "most men are boys until they are thirty, and little boys until they are twenty-five;" and this accords with the standard of manhood wh ch was fixed at thirty among the ancient Hebrews and other races.

A Medico-legal Institute.—It is proposed to establish a medico legal institute in Paris. The building will be in immediate communication with the morgue by means of an underground passage (said to be a transformed sewer; but that is a detail), in which there is a tramway for the transport of bodies. The institute will comprise a toxicological laboratory, a work room, a lecture-room, a library, a museum, a post-mortem room with a small waiting room for relatives, and a room in which suspected persons can be confronted with their supposed victims.

Progress of Medical Science.

A Special Form of Phlegmon of the Neck.—Drs. Brousses and Brault describe a space of prismatic form, situated below the back part of the tongue and bounded in front by the hyoglossal and thyrohyoid membranes, and behind by the anterior surface of the lower and attached portion of the epiglottis (*British Medical Journal*). The upper boundary is formed by two membranous layers, one consisting of the lingual mucous membrane; the other and deeper layer of fibrous tissue. This cavity, it is stated, is divided into two lateral halves by a membranous septum, which seems to be an extension downward of the median glosso-epiglottidean ligament. This enclosed and divided space, which is called by the authors the glosso-thyro-epiglottidean cavity, may, it is stated, become inflamed, and thus give rise to diffused phlegmon of the neck. Phlegmon, when developed in this cavity, presents in its early stages a special set of symptoms, which may enable the surgeon to form a precise diagnosis. These characteristic symptoms, which in the course of the affection become associated with intense dysphagia, dyspnœa, and aphonia, are: 1, Spinal localization of the swelling and tenderness in the portion of the neck between the suprahyoid and infrahyoid regions; 2, a "woody" consistence of the swelling, due to the fact that it is closely and deeply limited by membranous walls capable of withstanding tension; 3, slight infiltration in the glosso-epiglottidean region, while the surgeon is unable to feel any elevation there, or any collection of effusion in process of formation; 4, absolute integrity of the root of the tongue, and of the pharynx. This form of phlegmon is a serious one, as asphyxia is threatened in an early stage of the affection, and septic poisoning at a later period. The treatment should consist, when the inflammation is still limited to the cavity, in thyrohyoid laryngotomy, and afterward, when the swelling has spread above the hyoid bone, and can hardly be distinguished from that of deep-seated phlegmon in this region, in a median incision carried between the geniohyoid muscles to the base of the tongue.

The Significance of Vaginal Discharges.—A leucorrhœa inodorous or of mild odor persisting during the climacteric, accompanied by increasing hemorrhage, is suspicious and demands investigation. A leucorrhœa profuse, of peculiarly fetid odor, grumous, excoriating, appearing early or late during the climacteric, with profuse hemorrhage, is reasonable evidence of cancer of the cervix. A leucorrhœa moderate in amount, ill-smelling (the peculiarly fetid odor of cancer of the cervix being absent), accompanied by hemorrhage, suggests cancer of the corpus uteri. A leucorrhœal discharge with hemorrhage containing material like the washings of meat is said to indicate sarcoma. A watery discharge, as a rule, occurring during menstruation, odorless, or of little odor, persisting, accompanied by profuse hemorrhage, indicates fibroids; with little or no hemorrhage, polypi. Profuse bloody discharges coming on gradually with declining menstruation, ceasing usually with the menstrual flow, point to fibroids. Persistent profuse discharges of blood occurring spontaneously, arising from sudden exercise or coition, occurring, as a rule, after the menopause, indicate cancer. A gradually increasing amount of menstrual flow is suspicious and needs investigating. Post-climacteric hemorrhages in a fibroma of the uterus of long standing form one of the principal grounds for the suspicion of sarcoma (Borner). The early recognition of malignant disease is demanded, and possible prevention of the fatal exhaustion which accompanies it by the administration of drugs, and the application of those methods which, in a measure, may be supposed to offset the terrific drain on the nervous system; inasmuch as present experience shows that early removal of diseased tissue prolongs life, the importance of early diagnosis and treatment can hardly be over-estimated.—*New England Medical Gazette.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, September 9, 1893.

THE PAN-AMERICAN MEDICAL CONGRESS.

THE meeting of this body, held at Washington during the past week, has, on the whole, been a success. The attendance has been gratifyingly large, nearly nine hundred delegates having registered by the morning of the first day. Of the seventy-two foreign delegates officially appointed, one half have been present, representing sixteen different countries. The extensive knowledge which many of them possess of the English tongue has been a gratifying surprise. They have all responded in a tone of lofty appreciation of the work of the Congress, and have made a most favorable impression upon their North American confrères.

One fault, not to seem ungracious, has been the multiplicity of the sections. In several instances several have been obliged to combine, owing to the slim attendance upon each singly. The American idea that "bigness is greatness" unfortunately too often creeps into our National scientific bodies. If the work of the Congress could have been condensed into half a dozen sections the results would have been, we believe, more satisfactory and more permanent.

The recommendations of the various sections looking toward the unifying of the medical interests of the two Americas are given in our accounts of the various sessions. They are well worthy of careful attention at the hands of the profession and the officials of our Government.

Undoubtedly the Congress, through its delegates, will do much to further all legitimate measures leading to closer affiliation between the countries represented.

Perhaps the most important point of domestic interest is the proposed enlargement of the American Medical Association, so as to have it assume a Pan-American character. This idea was a novel one to the Congress, but it seemed to meet with a cordial reception, and out of it conditions may arise of importance to the entire medical profession of the Western hemisphere.

To the local committee at Washington too much praise cannot be given. They have even surpassed their previous creditable record in this respect. While many of the officers of the Congress have spent the heated term by mountain and shore, the committee has remained at home and furthered every detail in arranging for a satisfactory meeting. Its success has been without a flaw.

As is usual in all gatherings fathered by the American Medical Association, the New York City representation has been conspicuous by its absence. There has been a fair attendance on the part of the younger men, but the older men have scarcely been represented at all. The reasons for this state of affairs are too well known to require mention here. Is it not time that a different order of things should be brought about?

The social features of the Congress have been gratifying from every point of view, and we are sure that all have left Washington feeling that the Pan-American assemblage has justified its organization.

THE MYSTERY OF CHRONIC CONTRACTED KIDNEY.

ONE death in every twenty is due to kidney disease. In adults the proportion is much higher. The interest in the kidney and its workings is, therefore, very great, not only in the profession but the laity. The liver kills its hundreds, the stomach its thousands, the kidneys their tens of thousands. Leaving out of consideration the mortality from intestinal diseases among children, one finds that the organ of least resistance is the lung. Lesions of this imperfect viscus are the cause of over one-fourth human mortality. The nervous system gives out next. Following this come the heart and kidneys, which are about equally active as agents in mortality. These facts suggest a possibility that people, including physicians, who are careful about their health think too much of their stomachs, their livers, and their constipation, and too little of the way in which the kidneys are behaving.

This is the teaching of a lecture on "The Mystery of Chronic Contracted Kidney, and the Secret of its Prevention," delivered by Dr. H. C. Wood, and published in the *University Medical Magazine*. We trust that the author is not altogether responsible for the title, which is somewhat expansive for a scientific publication, for we do not find that he has removed any new veil enshrouding the Isis of renal pathology and therapeutics. Dr. Wood, however, does show happily and impressively the fact that contracted kidneys often develop insidiously, perhaps by jumps and starts, and in unexpected ways; also that the causes may be poisons engendered within from over-feeding, mal-assimilation, indigestion, etc., as well as from exposure to the ordinary extrinsic poisons, such as alcohol and lead. One should watch the kidneys, looking out for temporary albuminuria, hyaline casts, and low specific gravity. The writer gives this impressive illustration:

"Some years since, one of the most graceful lecturers who ever adorned a chair in the Medical Department of the University of Pennsylvania had occasion in the lecture-room to use in a control experiment normal urine, and selecting his own for the purpose unexpectedly found that he was the subject of chronic Bright's disease. He had supposed himself in perfect health, but not very many months later died of uræmia. Such an occurrence as this," Dr. Wood adds, "parallels what happens not very rarely in the daily routine of medical practice. Every practitioner who sees much of chronic diseases must, time and again, meet with cases in which contracted kidney is not detected until the later stages of the disorder are reached."

As for the secret of the prevention we find that Turk-

ish baths, habitual bathing, exercise, and moderation in eating are recommended. And no one can take exception to such advice.

DANCING AND GYMNASTICS.

Instructors and students of the physical education of women were quick to see that the various forms of "skirt dancing" which have so taken public fancy had value as gymnastic exercises. Certain modest modifications of this style of rhythmic motion have been introduced into the gymnasiums, and with excellent results. Young people soon get tired of the inanities of wands, wooden dumbbells, and of mechanical movements to the strumming of an asthmatic piano. The more there is of a dance movement to calisthenics, therefore, the better the exercise is liked and the more useful it becomes. The dancing academy could be made the best of gymnasiums, if it were ever properly ventilated and the pupils were properly dressed and under intelligent control. As this is impossible, the most feasible thing now will be to inoculate our gymnasiums for girls and women with more of the dance movements. Our youth would not only gain strength, agility, gracefulness, and health, but would learn to distinguish what is beautiful in dancing movements from that which is coarse and vulgar.

Miss Kate Field, who is observant and sincere, has taken some such position as this in her *Washington,* and pays particular attention to the value of the movements of the trunk as illustrated in the Spanish and Egyptian dances. "The mid-Orient," she says, "confines dancing to abdominal gyrations, marvellous as gymnastics and absolutely impossible to women who have ever worn corsets. Such development and control of abdominal muscles as are exhibited by the dancing-girls in Chicago-Cairo would, if possessed by American women, be the salvation of the race. Invalidism would be impossible, and children would be born healthy. Other than as gymnastics the *danse du ventre* has no interest whatever. It has neither grace nor beauty, the dancers are not attractive, and their persisting in wearing French heels denotes incapacity on their part to appreciate the eternal fitness of things. Vulgar men and women who have set up a howl against this performance would do well to look around the American ball-room and dinner-table and discover like food for prurient fancy."

THE AUTUMNAL TYPHOID.

It will be contrary to former experience if the present autumn does not bring with it the usual increase in the number of typhoid-fever cases. This condition of things is so uniformly associated with the return of our summer tourists, that we cannot escape the conviction that they bear a direct relation to each other. In fact it would seem strange that the case should be otherwise, considering the dangers from bad drinking-water to which the ordinary summer boarder is exposed, even in what are styled first-class rural hotels. This latter danger has been especially emphasized by the existence of a prolonged drought, in which the wells and springs have suffered from lack of suitable supply, besides being the ever-ready absorbers of foul soil drainage, and the natural carriers of the numerous and deadly pathogenic fever-germs.

The farm-house boarder, however, is the one most to be commiserated on the dangers which he must have necessarily faced in his yearning for the quiet and repose of strictly pastoral surroundings. The simple fare of milk, eggs, and fresh garden sauce may tend to give recreation to the overtaxed metropolitan stomach, and the moss-covered bucket may suggest the poetical sufficiency of satisfied thirst; but these will hardly offset the baleful proximity of the embowered out-house at the end of the short board walk, or its odoriferous suggestiveness in his raftered garret dormitory. And yet this is the rule in so-called country boarding-places, which are so freely advertised, and, alas! so readily patronized by the great majority of those who go for health and recreation. Numerous summer resorts in this and other States have had typhoid fever constantly in their vicinity, and have been sowing the seed for the autumnal city harvest with a surety that will without doubt be manifest as the season progresses. We trust that we shall be agreeably disappointed, but we must wait and see.

THE SUN IN SURGERY.

Dr. D. V. Thayer, of San Francisco, after trying heated needles, endermic needles, croton-oil, Baumgartism, and caustics, has come to the conclusion that the solar rays are the most efficient of all surgical methods in the treatment of "capillary aneurisms, varicose veins, indolent, chancroidal, and rodent ulcers; epithelial cancers; birth, India-ink, and powder marks; bleeding vessels and surfaces, hemorrhoidal and erectile tumors, morbid growths, such as warts, moles, small wens, and all diseases of the skin of a parasitic nature."

This is claiming a good deal for the sun, which though a large and important body has not heretofore made any pretences to surgical pre-eminence. Dr. Thayer admits that he is not the first to discover the surgery and dermatology of the sun. Some years ago a London surgeon, by using the sun's rays, succeeded in removing a wine-mark from the face of a lady, and also succeeded in destroying a malignant growth with the same remedy. The wound healed readily, and up to the time the article was published there had been no symptoms of the disease returning.

Dr. Thayer does not seem to know of the improved methods of using the sun devised by Count Mattei. That ingenious old gentleman bottled up the solar rays and sold them in solution, to be taken internally *ter in die*. However, the San Francisco physician seems just as confident of his more open procedure. He says (*Pacific Medical Journal*): "During a practice of more than a quarter of a century I have found no caustic or cautery to compare with solar heat in its beneficial results. Unlike other caustics, it can be applied with perfect safety upon the most delicate tissues and is at all times under the control of the operator. It has other advantages—the system receives this treatment kindly. The irritation and inflammation following its application are surprisingly slight and of short duration. Another point in its favor, the pain subsides immediately upon the removal of the lens. I have burned the skin of nearly the whole of one side of the face at one sitting, destroying the cuticle; within five minutes the burned surface

would be free of pain. There is a curative power in the chemical rays of the sun, yet unexplained. I avoid blistering, carrying the burning beyond this point, carbonizing the tissue."

Dr. Thayer tells us of his wonderful results, but does not describe his technique. Hence we grow somewhat suspicious, and are less surprised to hear his admission that he has been called a quack.

We find nothing of quackery in his article, but it is difficult to understand how thermic rays from the sun have a different therapeutic effect from those of an electric cautery.

The specialty of using the sun in surgery will, at any rate, be confined to the Pacific coast, where the sun shines every day in the year for nothing.

THE CHOLERA PROSPECTS.

It was at this season last year that the public was startled by the threatened invasion of our port by cholera. So far, however, we are safe. Our quarantine has been efficient and no case has appeared in this city. The prospects are exceedingly good that we shall escape altogether. The promptness with which our health authorities follow the clew of suspicious cases, and the radical manner of isolation, give the best possible guarantee that public confidence in the efficiency of our sanitary regulations will be fully and satisfactorily maintained. Considering, however, the continued prevalence of the disease in nearly every country of Europe, its ravages in Russia, Egypt, and Arabia, there is every reason for the exercise of the utmost vigilance on the part of the authorities. The sporadic case in Jersey City was an ominous warning as regards possibilities, which, but for the watchful interest of Health Commissioner Edson and his prompt rendering of assistance, might have remained unheeded and have resulted in a more or less wide-spread dissemination of the disease.

The earnest desire of the Health Officer of the Port to co-operate with the National Quarantine authorities tends in the right direction to steady public confidence and to make efficient the present quarantine laws. The ports to be feared at present are Antwerp, Rotterdam, and Marseilles, and these are most effectually under control, not only by our quarantine officers at home but by our consular quarantine abroad. Again, the sanitary authorities of all the countries of Europe and Asia are so thoroughly alive to the necessities of the situation that the extension of the plague will be intelligently combated as it never has been before.

Objections to a Laboratory.—The Japanese government has established a laboratory for the study of infectious diseases in Tokio, to be under the direction of Dr. S. Kitazato. The inhabitants of the ward in which it is intended to build the laboratory are, however, greatly opposed to it, as they fear that it will injure their business and cause a depreciation in the value of real estate in the neighborhood. They have united in an appeal to the government to change the site for the proposed establishment and place it somewhere in the outskirts of the city.

News of the Week.

A Somnambulist.—A man, eighty-eight years old, recently walked off a train going at the speed of fifty miles an hour, near Plainfield, N. J. He was asleep at the time, and though rolled over several times and somewhat bruised, he was apparently not seriously injured when picked up.

The Diagnosis of Diphtheria.—Dr. H. M. Biggs has submitted a report to the Board of Health of this city concerning the bacteriological examinations made in suspected cases of diphtheria. The examinations were begun early in May. Arrangements were made with a number of druggists in this city to keep on hand a supply of culture tubes furnished by the department. These tubes are furnished without charge to physicians who desire to make inoculations themselves in suspected cases. After inoculation the tubes are returned to the station from which they were obtained and are collected by the department collector. A report of the examination is forwarded the following morning to the physician. Department inspectors will make the inoculation when physicians request it. Of the 431 cases thus far examined about one-third proved to be false diphtheria. Dr. Biggs says in his report: "These investigations have shown that a considerable proportion of the pseudo-membranous and exudative inflammations of the throat and upper air-passages, commonly considered as diphtheria, and having the anatomical appearances found in diphtheria, are not true diphtheria, but are of a far less serious nature. These latter cases may be called false diphtheria. In true diphtheria the mortality is very high, and the danger of transmission to others is great; in false diphtheria the mortality is very low, and the danger of infection slight. The differentiation between true and false diphtheria, though often difficult or impossible without the aid of a bacteriological examination, can in this way be made within a few hours. Cases which prove to be false diphtheria will not receive further detailed attention from the Health Department. Cases, on the other hand, which prove to be true diphtheria will be subjected to the usual rules and regulations covering contagious diseases."

Contagion from Kissing.—A telegram from Jamestown, N. Y., says that at a wedding in a village near that place a number of friends kissed the bride, who was suffering from slight sore throat at the time. Since the wedding the case has been found to be one of diphtheria, and a large number of those who embraced the bride when offering their congratulations have been attacked by the disease. No deaths have yet occurred, but many of the cases are said to be very serious.

Five New Cases of Small-Pox have appeared in this city during the past week.

The American Social Science Association.—In the Education Department of the American Social Science Association, which had its day at Saratoga on September 5, 1893, Mr. Hamilton W. Mabie, editor of the *Outlook*, made the opening address. This was followed by papers on "The Seamy Side of the Kindergarten," by Edward Fisher, of Berkshire, Mass.; "American Colleges and their Work," by Dr. G. Stanley Hall; "The Education of Epileptics," by Dr. Louise

Fiske Bryson, and "Turkey and Civilization," by the Hon. Oscar Strauss. In the Health Department, September 6th, Dr. Frederick Peterson delivered an address on "Recent Progress in Medicine and Surgery."

New Quarantine Regulations.—The Treasury Department has just issued a new order, based upon the act of February 15th last, which grants additional powers to the Marine Hospital Service. The first article of the regulations provides for the inspection of all vessels from domestic ports where yellow fever, cholera, typhus fever, or small-pox is prevailing. The new regulation authorizes the Supervising Surgeon-General, from time to time, personally or through a duly detailed officer, to inspect the maritime quarantines of the United States, State and local, as well as national, for the purpose of ascertaining whether the quarantine regulations prescribed by the Treasury Department have been or are being complied with. These officers are authorized to board any incoming vessel, or any vessel detained at Quarantine, and to examine all portions of the Quarantine establishment for this purpose, with a view to certify, if need be, that the regulations are being enforced.

Superintendent Kimball, of the Life-Saving Service, issued an important circular letter, September 4th, to all keepers of life-saving stations on the Atlantic seaboard, and especially to those in and about New York. The circular instructs the officials of the Life-Saving Service to co-operate with the officers of the Marine Hospital Service in preserving a strict quarantine on infected ships. To this end the surfmen are instructed to keep a close lookout for all matter, such as bedding, clothes, vegetable matter, etc., which may wash ashore. This matter they are directed to handle with rakes only, to dry and burn it. They are also instructed to see that no persons who may escape from ships detained at Quarantine are permitted to land. In a general way the Life-Saving Service will assist all in its power to maintain rigid quarantine when it is established, so as to lessen the chances of infection to this country through the means of diseased household articles.

Improvement of Naval Hospital.—Surgeon-General Tryon of the Navy has at his disposal $90,000, as a part of the share of his bureau for the sale of land in the Brooklyn Navy-Yard two years ago, which he proposes, with the Secretary's consent, to expend in improving the Naval Hospital, and with the addition of an appropriation Congress will be asked to make, to add two sick wards to the present structure, to modernize the service and put it on a footing with other large hospitals of the country. The present hospital was built fifty years ago, and is entirely inadequate for the demands of the service. It is the largest in the navy, but is still behind the advances made in other hospitals for caring for the sick in large numbers.

An Active Industry.—The demand for skulls and skeletons is said to be always in excess of supply, particularly at this time of year. It may interest our readers to know what are the current prices in the American market.

Half skeleton, disarticulated, in box, consisting of the skull, the spinal column, twelve ribs, pelvis, one arm, and one leg. The bones of the spine, hand, and foot are held together by catgut	$21 00
Articulated skeletons to suspend, male or female	$30 00 to 40 00
Articulated skeletons with stand	35 00 to 40 00
Fœtal skeletons, ass. ages, on stand under glass, each	10 00
Disarticulated skulls, in box, with compartments for each bone	$12 00 to 15 00
Entire skulls, plain	6 00
Entire skulls, one cut horizontal	7 00
Entire skulls, two cuts, one horizontal, the other vertical	9 00
Entire skulls, five cuts, showing nasal cavity and sinus	15 00
Entire skulls, seven cuts, showing the ear complete on one side	20 00
Skulls, disarticulated, and all the bones united with polished metal strips according to Beauchene's method. By turning a screw the front part moves forward and the back part backward; the lower jaw can be removed. Each bone can readily be studied separately, including those of the ear. Price, under glass	40 00
Internal ear, semicircular canals, cochlea, etc., on stand	6 00
Fœtal skull	2 50
Hands and feet, articulated with catgut	2 50
Pelvis, female, with ligaments	10 00
Pelvis, female, without ligaments	7 00

Obituary.

JOHN WILLIAM BRANHAM, M.D.,

ASSISTANT SURGEON MARINE HOSPITAL SERVICE.

Assistant-Surgeon John W. Branham died of yellow fever at Brunswick, Ga., August 20th. He was taken ill about August 10th, while in the performance of quarantine duty at Brunswick, and died on the afternoon of the 20th.

Assistant Surgeon Branham was born in Walker County, Ga., October 27, 1868, and his early education was derived from the schools of his native State. When he was thirteen years of age he moved to Baltimore, Md., and received a general education at the Baltimore City College. He then studied medicine at the College of Physicians and Surgeons, Baltimore, and graduated at the head of his class from that institution, March 13, 1889. During this time his elder brother, Dr. J. H. Branham, of Baltimore, was his preceptor. After graduation he first served as resident physician at the City Hospital in Baltimore during part of 1889 and 1890, and afterward was assistant quarantine physician for the port of Baltimore from May until November, 1891. Leaving Baltimore he moved to Kempsville, Va., where he practised medicine until entering the medical corps of the Marine Hospital Service. At the examination of candidates held in Washington, D. C., in March, 1893, Dr. Branham passed first among twenty-two applicants, and was commissioned Assistant Surgeon, April 19, 1893, and on April 21st was ordered to the Marine Hospital, Stapleton, Staten Island. On July 25th Assistant-Surgeon Branham was ordered to Brunswick, Ga., to take charge of the quarantine at that port, where he remained in the active discharge of that duty until he was stricken down with yellow fever.

Surgeon-General Wyman pays the following fitting tribute: "As an officer Assistant Surgeon Branham was held in high esteem, both by those under whom he served and by the Department. His ability was fully recognized, and he was chosen for the important duty of reorganizing the quarantine of Brunswick and establishing it upon a firm sanitary basis, the local quarantine at that point having proved to be insufficient. Through his death the Service has lost an able officer.

"Personally Assistant-Surgeon Branham was a man whose general education and medical attainments won for him the highest respect, and his social relations with his brother officers and others were characterized by a manliness of deportment and gentlemanly bearing that won the affection of all."

Society Reports.

Pan-American Medical Congress.

First Meeting, Held at Washington, D.C., September 5, 6, 7, and 8, 1893.

(Special Report to the MEDICAL RECORD.)

FIRST DAY, TUESDAY, SEPTEMBER 5TH.

THE meeting was called to order promptly at ten o'clock by the President of the Congress, Professor William Pepper, M.D , LL.D., of Philadelphia. Prayer was offered by the Right Rev. William Paret, D.D., Bishop of the Episcopal diocese of Maryland.

Address by President Cleveland.—The Congress was formally opened by Honorable GROVER CLEVELAND, President of the United States, who said : " Few words are necessary from me on the present occasion. I am only glad of an opportunity to say how pleased I am to be in any way related to such an Association as this, assembled for the furtherance of the highest and noblest aims which can actuate mankind—the protection of the public health and the prevention of contagious and epidemic disease. Where more properly can such questions be discussed than at the capital, of a nation which appreciates all which pertains to the commercial relations and easy intercourse between the different nations of the Western world? Where can the question of the alleviation of human suffering be more fittingly considered than at the capital of a nation whose highest aim is the welfare of the individual? It only remains for me to declare the Pan-American Congress open for the transaction of the business which has called it together."

Address of Welcome.—An address of welcome was delivered on behalf of the District of Columbia by Honorable JOHN W. ROSS, LL.D., President of the Board of Commissioners, D C. He said that for the first time there were here gathered together representatives of the medical profession from all the countries of the two Americas. Particularly fitting was it that such a meeting should be held in a district named after the great discoverer, and in a year when the nations of the earth were doing honor to his memory. The spirit of the age demanded much of the physician, and its members were here assembled not for individual aggrandizement, but for the loftier purpose of extending the sphere of medical knowledge and for the prevention of human suffering. From a consideration of the regional characteristics, the climatic conditions, and the general environment of mankind in the countries here represented, there could be an interchange of experience and observation never before possible. He urged that plans be formulated to establish international quarantine and to check the progress of contagious diseases.

Furthermore, all municipal authorities faced a serious problem in the matter of location of pest-houses for such maladies. Such buildings must be near enough to avoid long transportation of the sick, and yet must be within proper reach of a sewerage system and an uncontaminated water-supply. Experience had shown that there was in every community a dread of such institutions amounting almost to a panic. If it be correct that such hospitals, when properly erected and managed, are not a menace to the community, it was the privilege and the duty of this Congress to relieve the public mind of its apprehension, and an authoritative assertion to such an end would do more good than could be done in any other way.

Moreover, the result of the deliberations of the Congress would be not only the formation and renewal of friendship, but would show to the world that beneficence and philanthropy were not measured by national boundaries, but were as long and broad as humanity itself.

He expressed the hope that the present was but the forerunner of many similar gatherings, so that the common interests of all the Americas might be best subserved. The District of Columbia felt honored at being selected as the place of meeting, and on behalf of its citizens he extended to all the delegates a cordial welcome.

PRESIDENT WILLIAM PEPPER made a few general remarks defining the general scope of the Congress. He stated that the official invitation extended by our Government had been in every instance accepted, and that the official delegates were on hand. He called attention to the large conception in the public mind of the importance of the work of the present meeting. We were on the brink of a larger conception of what America really is, with a destiny and international relations which necessitate united action. He expressed the hope that the Pan-American Congress and the American Medical Association might eventually become welded into one compact body.

A response was made on behalf of the British West Indies by DR. JAMES W. PHILLIPPO, of Jamaica, who said that his island home, while from the British point of view the key to the Gulf of Mexico, was also an outpost of the United States, and pledged himself to do all in his power to further the mutual hygienic interests of the two localities. He hoped for a closer relation between the Hydrographic Bureau in the United States and that of Jamaica, so that the former could be forewarned of the approach of violent storms.

A few remarks were made by Hon. J. B. MCCRARY, of Kentucky, who introduced in the House of Representatives the original bill which led to the establishment of the Congress.

DR. MONTIZAMBERT, of the Grosse Island quarantine station in the St. Lawrence River, responded for British North America, alluding to the conferences which had been held between Canada and the United States through the medium of the American Public Health Association, and to the value of having, as was now the case, health representatives of each country at the ports of the other.

A response was made on behalf of Costa Rica by DR. CALORA, who hoped that the protecting wings of the American eagle would be spread over the smallest of the Western republics.

DR. JAMES W. HIBBERD, of Indiana, President of the American Medical Association, said that the latter was the parent of this and all similar organizations in this country, and had encouraged their organization. Speaking for the body over which he had the honor to preside, he re echoed the wish that the closest relations might exist between it and the present Congress.

The report of the Secretary General was made by DR. CHARLES O. L. REED, of Cincinnati, who said that the present condition of the Congress and its official handbook must constitute his report. He stated that much credit was due to Hon. John Sherman, who had managed in the United States Senate the passage of the bill which led up to the present gathering. The meeting was in reality a governmental protégé, while embracing through its delegates a constituency of over one hundred and fifty thousand physicians.

DR. S. S. ADAMS, of Washington, Chairman of the Local Committee, made a report in which he stated that Senator Gorman, of Maryland, was largely instrumental in the passage of the bill securing the necessary appropriation for expenses.

The Flora of America in its Relations to Medicine.—The formal address of the session was made by PROFESSOR FRANCISCO A. RESQUEZ, of Caracas, Venezuela, on this subject. The inorganic kingdom he said has yielded to the organic in therapeutic importance. The tendency of modern medicine is to employ, not internal remedies which act mechanically, but rather those which are represented in the structure of living tissue. Only those metals should be retained in medicine which have their representatives in the living body. The living elements of organized tissues require organic remedies.

The speaker gave an interesting catalogue of the different vegetable remedies in common use which grow in the various South and Central American countries represented

in the Congress. Quite a number of them, some credited with remarkable properties, were unfamiliar to his auditors. He expressed the hope that a society might be formed for the study of the American flora in its relation to medicine, having its home in this country and branches in the various Southern republics.

SECOND DAY, WEDNESDAY, SEPTEMBER 6TH.

The general session was opened at 9.15 A.M., with prayer by REV. P. J. GARRIGAN, D.D., Vice-Rector of the Catholic University of America.

Brief addresses were made by DR. VICTOR LUIS JILLES (in French), representing Hayti; DR. GREGORIO MENDIZABAL (in Spanish), of Orizaba, Mexico, on behalf of that country; DR. MANUEL A. MUÑEZ (Spanish), representing Peru, and DR. PEDRO LA GLASA, of Buenos Ayres, representing the Argentine Republic. The latter gentleman was obliged to travel thirty days in order to be present.

Gangrene — Its Pathology, Symptomatology, and Treatment.—This was the title of the formal address of the session, and the paper was read in English by PROFESSOR RAFAEL LAVISTA, M.D., of the City of Mexico. Gangrene, he said, could be divided into two varieties, septic and aseptic. He confined his attention to a consideration of the form occurring spontaneously. He traced the gradual development of the train of pathological sequences, starting with the first impairment of the endothelium lining the vessel, and ending with its partial or complete occlusion. Allusion was made to the various modifications of the process which the peculiar anatomical relations of each part might determine.

A careful analysis of the symptoms and signs of the disease was given, and the general methods of the treatment by modern surgical procedures were outlined.

THE PRESIDENT stated that in view of the importance of continuing the inter-continental work so auspiciously begun, it was advisable that the International Committee of the Congress should be empowered and requested to secure proper governmental recognition, 1st, for the necessity of preventive medical measures; 2d, for the necessity of a uniform American Pharmacopœia; and 3d, for the elevation of the standard of medical education.

A motion to this effect was introduced and carried.

A resolution was introduced by DR. J. D. BROWN, of Texas, relative to the matter of urging upon certain governments the importance of sanitary work. Especial stress was laid upon the matter of Dr. Ernest Hart's recommendations relative to sanitation in India, the home of cholera. By the rules of the Congress this resolution was referred to the International Committee, as was also one adopted by the Section on Hygiene, Climatology, and Demography, relative to the importance of a cabinet health officer in each country. According to the terms of the resolution such an office should be national in character. Its incumbent should have a parity of voice and vote in the national councils. He should exercise an independent executive authority comparable to that of other cabinet officers, and finally should be an educated and experienced medical man.

The Chairman of the Local Committee of Arrangements for the meeting of the American Medical Association at San Francisco, in June, 1894, was introduced, and outlined the work already accomplished. He promised abundant hospitality, a good attendance, and a successful gathering.

EVENING SESSION.

The session was devoted to the President's Address, by DR. WILLIAM PEPPER, of Philadelphia, which in substance was as follows:

A Fitting Year for the Congress.—In view of the history of the organization of this Congress you will not, then, think it strange that, called upon to address such an assemblage in this Columbian year, it should seem less fitting to dwell upon any technical topic than to turn our thoughts to the state of this continent and of its aboriginal inhabitants at the time of its discovery by Columbus, and to the obstacles which opposed him and the great men who completed his work. For these have had a bearing on the racial developments which have since occurred here, and should be held in mind in any estimate of the progress we have made during the subsequent four centuries.

Its High Aim.—This Congress represents much more, however, than our common interest in medical science and the common feeling of brotherhood which animates the entire profession. It is, indeed, it always has been, and forever may it so continue, the glory of the medical profession that their allegiance is one and undivided, for their service is solely in the cause of truth and humanity. Dynasties have risen and crumbled, the map of the world has been changed times almost without number, but the march of medical science through the ages has been ever onward and upward toward those lofty goals —the prevention of disease, the relief of suffering, the improvement of the race.

Common Racial Peculiarities.—The aborigines who were living on this continent at the time of its discovery by Columbus presented, it is true, considerable differences in the stage of development they had reached, as well as in their language and even in their appearance. There are long intervals of social development evident beyond the squalid sty of the California savage and the great structures of Zuñi. Yet in all of them can be demonstrated an underlying principle of adaptation to a certain mode of communal life, such as all American aborigines are believed to have practised. The various tribes had their distinguishing characteristics, but all possessed the cinnamon colored or copper colored complexion; the high cheek-bones, and small, deep-set eyes; the straight, black hair, with scanty or absent beard.

There seems to be but little doubt that had America not yet been discovered there would have been going on here, for the last four hundred years, a slow and irregular approach to a higher social condition.

Franklin's Foresight.—Benjamin Franklin was one of the first to foresee the close reciprocal relations which would inevitably arise between the countries of the two Americas, and in 1749 he embodied in his plan for the organization of the University of Pennsylvania an earnest advocacy of the thorough teaching of the Spanish and Portuguese tongues.

The more closely the period of the Middle Ages is studied the more do we appreciate the magnitude and the necessity of the changes effected during those centuries in preparation for the splendid activities of the Renaissance. The mission of the Middle Ages had been really, though not obviously, a cosmopolitan one, and it was fitting that the noblest achievement of the Renaissance should be the discovery of America.

The Discovery of America and Medical Science.—In no respect may the discovery of America be regarded as the dividing-line between the Middle Ages and the Modern Era more truly than in regard to medical science. In spite of the prodigious learning of the most distinguished Arabian and Jewish physicians their medical science was far too largely speculative and philosophic. Great universities were established, some of which possessed regal revenues and magnificent libraries. Numerous hospitals were founded, of which the large and wealthy one established at Cairo in 1283 merits special mention. But the outcome of this long dominion of the Arabs and the Moors, so far as concerns medical science, was merely a marked advance in chemistry and pharmacy, the introduction of many new remedies, and the advocacy of the union of the natural sciences with medicine. Their chemistry was tinctured strongly with alchemy, their clinical teaching was elementary, their diagnosis and treatment lacked the true Hippocratic force and directness.

The history of European medicine for more than three

hundred years is a record of which we may well be proud when the enormous obstacles to progress are held in view. It is not necessary to remind this audience of a single one of its great triumphs. But it is sad to reflect upon what has been done as contrasted with what might have been.

Achievements of American Medicine.—In 1765 the University of Pennsylvania established the first medical school in the United States.

I cannot detain you by an enumeration of the services already rendered by America to medical science. Almost immediately after the Discovery important contributions to pharmacology were announced, chiefly from South America, and from the introduction of guaiacum, in 1508 until now these contributions have become more and more frequent. The entire medical world was agitated during the latter half of the seventeenth century by the struggle over the merits of cinchona bark. Among the results which may be anticipated from this meeting is, I trust, the adoption of some well-considered plan for systematic conjoint study of our American remedies and their pharmaceutical preparations, looking to their scientific classification, to greater uniformity in their preparation, and ultimately to a single Pharmacopœia for the entire continent.

The introduction of nitrous oxide (1844) and of ether (1846) into medical practice, with which the names of Wells and of Morton are so honorably connected; the establishment of the operation of ovariotomy by McDowell, of Kentucky, upon a secure scientific basis—these and hundreds of other achievements of lesser brilliance are too familiar to need mention.

American Medical Literature.—In the production of medical books America is behind other countries, while in the more ephemeral forms of medical literature she leads the world.

This Congress meets at a period of peculiar and critical interest in medical education, and I am glad to say that for the first time in the medical history of the United States we may feel proud to have such a meeting convened here, and to invite a close examination of our educational standards and facilities. I should fail in courtesy and in candor alike were I not to acknowledge the great value of the example which has been so consistently set by Latin-America and by Canada in the maintenance of a high standard of qualifications for medical practitioners.

Its Future.—A broad field opens before us for the study, with the aid of collective investigation, of the distribution and course of phthisis and rheumatism and other important diseases as influenced by race and locality. The endemic fevers, other than malarial and typhoid and yellow fever, which are said to prevail in various parts of North and South America, have long demanded systematic investigation to complete the study which the illustrious Drake began. We shall now have the opportunity of studying, equally by means of collective investigation, the relative effects of various climates on the numerous races now represented in America, and of determining more accurately the scientific and practical questions connected with our extensive series of health resorts which embrace the finest examples of every type. There are, indeed, none of the sections provided for in this Congress from whose work more valuable results should follow than from those on medical pedagogics, on hygiene and climatology, and on quarantine.

Education of Public Sentiment.—Everyone knows now that the most dreaded diseases are inseparably connected with definite organisms, that these organisms have special laws of development and distribution, that to destroy or exclude them is to avoid the disease, and that to tolerate conditions which favor their development is to encourage and invite the attack of the disease. When these simple, demonstrable propositions are considered in connection with such scourges as cholera and yellow fever, and typhus and typhoid fever, and scarlatina and diphtheria, and epidemic meningitis, it needs no further argument to prove the value and the necessity of quarantine, and of efficient medical inspection and protection. Nor does it need further argument to show the wisdom of establishing laboratories of hygiene at many points over the country, of equipping them amply with the ablest men and the finest apparatus, and of endowing them liberally, so that the search after the yet unknown causes of disease, and after the best methods to prevent the development of such causes as are known, may be prosecuted with ceaseless vigor.

To attain these ends is the last and greatest service to be rendered to science and to the nation by our Congress. Our combined influence will be irresistible when used in advocacy of higher education; in carrying out large plans for the scientific study of our national life, as affected by social and climatic influences; in the adoption of remedies and remedial measures of demonstrated merit, and in the insistance upon a fuller recognition of the lofty function of preventive medicine. "Salus Sanitasque Reipublicæ, suprema lex." Let us acquire here a closer touch with each other, a deeper faith in our profession and its noble destiny, and a stronger determination to labor in brotherly co operation for the loftiest ideals of service to science and the race.

SECTION ON GENERAL SURGERY.

First Day, Tuesday, September 5th.

John B. Hamilton, M.D., LL.D., of Chicago, Ill., President, in the Chair.

Address of the President.—Colleagues, for the first time in the history of the American Continent, the medical men of the Americas meet for the purpose of scientific advancement and the cultivation of closer relationship. The countries of Washington, the land of Bolivar, and the sunny islands of the Southern seas, send their representatives to this capital of their oldest republic.

Our statesmen long desired close union between the American republics, and the medical profession have always stood ready to carry out their share of the patriotic duty; and we are inaugurating the first of what we hope may be the beginning of a series of Pan-American Congresses.

The rapid evolution of surgical knowledge is one of the wonders of this remarkable age, and surgeons may fairly claim that their own branch of the profession has kept pace with the stupendous advance made by the collateral sciences.

The labors of Darwin,* Huxley, Herbert Spencer, Pasteur, and Lister, in the last decade, have made possible the practical sucesses of the present decade.

There is at this time no organ or tissue of the body removed from the remedial scalpel, and the questions presented are rather those of method than those of original discovery.

Surgical Bacteriology.—This study, which includes that of microbic products, has still much to disclose, but we base our practice upon the immortal discovery of Pasteur.

Antiseptics of the Ancients.—The vulnerary compounds of the ancients were largely composed of what we now know as antiseptics. The terebinthinate and metallic dressings of the Alexandrian period, we can accept to-day as true antibacillary agents. The red hot iron and boiling oil of the ancients may be said to have formed a true aseptic eschar. They knew nothing about aseptic surgery. They were ignorant of causes, all they were interested in were the good results obtained. While bacteriology has added much to our knowledge of tuberculosis, though still less of carcinomata, the treatment of both still remains unsatisfactory, and as yet no Pasteur or Harvey has dawned upon our horizon to unveil the mystery to which heaven has not given this generation the key.

Through improvements in technique, etc., in all prob-

ability tuberculosis and carcinoma will be classed among the preventable diseases. Either of these two diseases alone causes more deaths than yellow fever and cholera combined, yet no government has set on foot any systematic or scientific inquiry as to its causation or propagation. Much, however, has been done by the Bureau of Animal Industry in studying and preventing animal tuberculosis, but among human beings practically little or nothing has been done.

A Brief Splint Technology for Surgeons.—After the President's Address the afternoon session opened with the reading of a paper with the aforesaid title, by Edward A. Tracey, M.D., of Boston, Mass.

The objects of this paper are to treat in detail of a new material and method used in surgical splint making, to urge the surgeon to become the maker of suitable splints for cases occurring in practice, and to indicate lines of procedure in apparatus-making, which promise rich results in general and orthopedic surgery.

Material.—Its basis is wood pulp, made preferably from the crushed fibre of the poplar tree. It is rolled into sheets in such a manner that the fibres intertwine loosely in every direction, thus giving an increased ductility to the product. These sheets are further strengthened by having a fabric introduced between the layers of the pulp, or by interweaving with the short, crushed wood-fibres a long jute or other tough fibre. These sheets are made of several thicknesses, which I shall designate by number for convenience, each figure representing one millimetre. Thus, sheet No. 1 has a thickness of one millimetre, sheet No. 2, of two millimetres, and so on.

The characteristics of this material are stiffness or rigidity when dry, and plasticity with toughness when moist. Its rigidity can be increased *ad libitum* by the use of a silicate solution as a moistener.

Applied over Irregular Surfaces.—A splint cannot be directly moulded over the ankle joint, owing to the great irregularity of the surface presented. This can be overcome in several ways. The anterior splint should be cut from sheet No. 1, and applied, after moistening, to the limb, taking care to keep the outer border in contact with the skin and the superfluous material pinched up between the thumb and forefinger, and a bandage applied to perfect the moulding of the splint. A second way is to cut away the superfluous material, bring the edges together, and retain them there by a strip of material over the cut edges.

Moisteners.—Water, or a stiffening solution, can be used to moisten the material previous to moulding. The advantage of water is its omnipresence, and with its aid a very serviceable splint can be made. Such a splint, however, is liable to be softened by the absorption of perspiration, or, on children, of urine; and for this reason, as well as cleanliness, it should be protected by a covering of oiled paper or silk, or mackintosh, or, best of all, by a coat of varnish.

Potassium Silicate.—A solution of potassium silicate has several qualities which render it the best of the stiffening solutions experimented with. Any desired degree of rigidity up to brittleness can be given the splint by using a silicate solution as a moistener. The stronger the solution the more rigid the splint.

In making a silicate solution, the best one for ordinary use is one made by taking seventy parts of the commercial solution sold to surgeons and adding thirty parts of water thereto. A splint rendered rigid in this wise is not affected by perspiration. Another quality, of exceptional advantages in compound fractures, is that this solution has strong antiseptic properties.

Dextrine.—This solution is made by mixing one-half pound of dextrine to a pint of water. A splint with this solution can be remoistened and remodelled, which is quite an advantage in many instances, as in cases where swelling disappears it can be brought into closer approximation. The dextrine can be carried about in powder form, and by the addition of eight grains of corrosive sublimate an antiseptic solution can be made at a moment's notice.

Manner of Moistening the Sheets.—This is most satisfactorily done by applying, by means of a flat paste-brush, the fluid used, on both sides alternately, of the splint-blank, and repeating until the proper amount of the fluid is absorbed.

Amount of Moisture.—Practice enables us to determine the exact amount of moisture suited for our purpose. As a rule, get just sufficient amount of moisture to render the blank somewhat flaccid. If too moist it becomes difficult to retain it in shape while drying, besides causing unnecessary delay.

The time required varies from ten to forty minutes, the thicker sheets requiring more heat. Any source of heat will answer, and while drying you should see that the desired shape is retained until permanently fixed.

Splint Headings.—I shall briefly consider their application to the human body, under the headings of: 1, head splints; 2, trunk splints; 3, upper limb splints; 4, lower limb splints.

The above simplicity of classification will be necessarily violated in specific cases where compound splints, embracing parts of different systems, are constructed. I shall briefly describe two splints.

Spinal Column Splint.—This is simple and cheap. The blank is cut from sheet No. 1, and the potassium salicylate solution used, and should envelop the patient's body once and a quarter around. The patient should be placed in same position as for a plaster jacket, with light woollen garments underneath, and bringing the sheet around the body. A hinge is made by bending the pulp until sufficiently broken. The surface should be pressed well into the hollow of the back, and superfluous material pinched or folded up as before described.

Forearm Splint.—This makes a very light and serviceable splint, and retains the bones in position without the annoyance of carrying a weighty, cumbersome splint; a simple palmar forearm splint answering in most cases.

In the discussion which followed, Dr. McLane, of Detroit, Mich., said as serviceable a splint as was necessary could be made extemporaneously from a roll of newspapers, which, as a rule, could always be found at hand; they were light, cheap, and could be moulded to suit all cases of forearm. In Colle's fracture an anæsthetic should be used, and when properly set no splint is required except a little plaster to give support where there is a tendency to displacement, and without a splint we are enabled to keep up passive movements of the finger joints, which we should always do to avoid contractions, etc.

Dr. Reginald Sayre, of New York City, said while the splint was a serviceable one, however, the crinkles and puckerings incidental to pinching up the folds when moist to make it fit the spine, would not make it a very comfortable surface for the crest of the ilium to rest upon. It could not be adapted closely enough to the body of a child with prominent bones to make it a comfortable support. It should be fitted to a model instead of the child, if you wish to make it accurate.

Second Day, Wednesday, September 6th—Morning Session.

Simplicity in Surgery was the title of a paper by Robert W. Johnson, M.D., of Baltimore, Md. Simplicity in all surgical operations is the one great thing which all should keep in view. The tendency of the present day appears to be for the majority of surgeons to add something new to an instrument or an extra twist to a suture, upon which he can hang his name. The immortality of any discovery is intensified by its simplicity. A surgeon should be able to devise plans so simple that his operation can, in an emergency, be done in a hovel as well as in the hospital. Do not understand me to say that I would do away with all precautionary measures; on the contrary, I would not sacrifice an ounce of care for a pound of simplicity; but strip all operations of useless,

cumbersome frills. We should use home-made appliances wherever we can, and there is nothing so variable as the so-called antiseptic treatment.

Surgical cleanliness is essential. Boiling is a practical germicide, and by placing your instruments, tray and all, in boiling water for a stated period you render them thoroughly aseptic, and this can be done in any kitchen. A brush and bichloride solution for washing the surrounding parts is all that is necessary. Should you wish to apply an antiseptic dressing, gauze wrung out in bichloride solution will answer nearly all purposes. Then render the hands aseptic and observe all ordinary laws of cleanliness.

Gun-shot Wounds.—What better treatment than leave the bullet alone, unless it carries with it some of the clothing or other septic material with it into the wound? I seldom rummage for a bullet unless complications are present other than the bullet itself.

Sutures.—New sutures are brought to our notice, lasting for a few days and then giving way to a newer one or bobbing up under a different name; but the simpler ones still survive.

Hemorrhage.—Various bands and appliances have been and are continually being devised for controlling hæmorrhage, but the Esmarch's band has come to stay, owing to its simplicity.

In the discussion which followed, Dr. Quimby, of Jersey City, remarked: "We need such wholesome criticisms. The complex preparatory arrangements made by some surgeons have often been a source of injury to the patient, by adding to the time consumed by the operation and keeping the patient under the influence of anæsthetics for an unnecessarily lengthy period."

Observations on the Rotary Lateral Curvature of the Spine with Special Reference to Etiology and Treatment was the title of a paper by Jacob Teschner, M.D., of New York City. The usually unsatisfactory results derived from the treatment of these cases indicate the importance of proper and early attention.

Etiology.—Occurs most frequently between the seventh and fourteenth years. Girls are more prone to this disease than boys. Why this is so has not been definitely determined.

Passing over the various well-known causes, I will consider but the following four, viz.:

1. Hereditary tendency. 2. General temperament, and the condition of the mind and nervous system. 3. Lack of development of the muscular system, and the general physical condition. 4. Habitual faulty position with superimposed weight.

Hereditary Tendency.—Frequently I find decided scoliosis in the mothers of girls brought to me for treatment.

General Temperament and the Condition of the Mind and Nervous System.—Most girls afflicted are apathetic, indifferent, lazy, and somewhat morose, and are disinclined to romp and play with the same vigor as their companions after school hours. The facial expression is frequently a vacant stare, with dropped jaw and open mouth, giving the patient a silly appearance; all of which changes after energetic treatment. There is a lack of co-ordinating power, making it impossible for some patients to fully extend an entire extremity. If the wrist is extended, the elbow is apt to be flexed. This lack of co ordination also disappears on treatment.

Lack of Development of the Muscular System and the General Physical Condition.—General muscular development is very poor, some of the muscles being almost rudimentary, and when suspended patients are rarely able to sustain their own weight. Physical condition is bad and associated with poor digestion.

Habitual Faulty Position with Superimposed Weight.—Resting the weight of the body more upon one foot while standing, or sitting more upon one buttock, permitting the shoulders to fall forward, permits a sagging of the upper portion of the body upon the lower, and twists the spine and trunk into a mild form of deformity, which, if persisted in, becomes permanent, by producing actual bony and ligamentous changes. Faulty sitting is more frequent than faulty standing and is particularly noticeable in the school room.

I here wish to call attention to the pernicious effect of long and continued school hours without intermission for play or calisthenics, and also the improper furnishing of school-houses with benches, chairs, and desks of a regulation size, regardless of the varying sizes of the pupils.

Treatment.—The first step is prompt removal of the causes. Deformities of all kinds should be corrected. Keep the child away from school. Attend to the general health. Frequent baths to improve the condition of the skin. Tonics, if necessary, to improve muscular and nervous systems, and by sufficient open-air exercise.

The patient should have a properly constructed chair to sit upon. The back of the chair should properly fit to the child's back, reaching to the shoulders, with the feet resting comfortably upon the floor. The patient should rest frequently by lying supine upon the floor, with lower extremities extended and arms fully extended above the head. Self-suspension twice a day should be advised.

Treatment of the Three Degrees of Scolioses.—1st. Habitual scolioses which can be obliterated by the voluntary muscular efforts of the patients. In these cases I rely entirely upon the general directions before described, and systematic and regular gymnastic exercises. I give no support of any kind, not even a corset, thus leaving the muscles which are being developed and strengthened by exercises entirely unrestrained and free. 2d. Scolioses unaffected by voluntary muscular efforts, but which can be reduced or obliterated by suspension of the patients. I adopt the plan of treatment as in the first class of cases, adding proper, light, and well-cemented plaster of Paris corsets while the patients are suspended, and cause them to be worn until they can correct their deformities through their own muscular efforts. Where the deformities are only reduced under suspension new corsets are applied from time to time, until at last the deformities can be entirely obliterated by suspension. 3. Scolioses where the deformities are fixed. To the treatment of the second class I add that of forcible daily twisting of the spine in compression of the ribs by the use of an apparatus used by Dr. A. Hoffor, of Würzburg, which is described in the "Zeitschrift fur Orthopædischer Chirurgie," 1891. The result of this treatment I am not, as yet, in position to speak positively, but I am led to expect a marked improvement from its use.

In the discussion which followed, Dr. Quimby, of Jersey City, thought the reason for the disease predominating among girls was owing to their faulty manner of dress compressing the vessels supplying the spinal column and thus cutting off its proper nutrition. I believe in giving the muscles full play, and so with the Sayre jacket, you must give the muscles play and not depend altogether upon artificial support in the treatment of the disease.

Dr. John C. Schapps, of Brooklyn, N. Y., agreed with Dr. Quimby, and from his experience would give the muscles exercise in preference to relying upon artificial support.

In closing the discussion Dr. Teschnor replied that he took away all artificial support as soon as possible, but at first artificial support is absolutely necessary until the bones are able to bear the weight of the body. My plan is to see that they get daily gymnastic exercise in a proper manner.

Causation, Pathology, and Treatment of Carbuncle was the title of a paper read by David W. Graham, M.D., of Chicago, Ill.

Afternoon Session.

Recumbency in the Treatment of Pott's Disease, was the title of a paper by John C. Schapps, M.D., of Brooklyn, N. Y., in which he says it is not alone the collapse of a cavity produced by disintegration which is the local determining condition of the deformity of

Pott's disease. The softened bone which surrounds for some distance and merges into the seat of actual destruction is squeezed out by longitudinal pressure, bent out by antero posterior leverage, and pushed out by direct backward pressure. To directly antagonize these deforming forces it is necessary to have a passive spine. Portative apparatus are limited in their efficiency by reason of the distance and heterogeneous character and mobility of the parts which intervene between their points of application and the lesion sought to be controlled, and are usually applied with a view to maintaining the activity of the spine as a support and a base for muscular exertion. Recumbency means more than simply putting a patient to bed. It implies the retention of the whole spine in the best possible position so that the separate parts remain unchanged, or subject to such changes only as the surgeon may make. When the patient is horizontal, the force of gravity which had acted when upright as a deforming agent can be converted into a reforming force. Direct backward pressure can be accurately antagonized. Muscular action and consequent interosseous pressure, now greatly reduced by the general condition of rest, can be overcome by fixation and by less traction than would be required to raise the weight of what were superincumbent parts. The spine thus relieved of the performance of all its active functions, and saved from all traumatisms except that of respiration, is placed in the best possible condition for repair. And, what is of great importance, fever and the drain of muscular spasm, pain and perverted nutrition, are met by a state of systemic rest. Clinical experience has demonstrated the truth of these theoretical considerations. When the proper conditions are maintained, patients are usually relieved of pain, sleep and eat well, and soon lose the drawn, old, tired expression so familiar upon the faces of those suffering from prolonged muscular spasm. The improvement in general health which they commonly make is, to those who have been burdened by the traditional fear of confinement, surprising. I believe that by systematic recumbency the course of the disease is materially shortened, much destruction is avoided and much deformity prevented. Another merit of this therapeutic measure is that its employment does not demand the mechanical skill and experience necessary to the successful construction and use of a portative apparatus. When a spinal brace cannot be readily obtained, recumbency may, if the mechanical conditions are carefully studied, be safely resorted to, until other arrangements can be made. Patients may be removed long distances with comfort and safety upon a frame.

The indications for recumbency are: 1. As a routine measure, as soon as a diagnosis of spondylitis has been made, or even when it is probable. 2. In cases of patients wearing braces, persistent pressure sores, progressive deformity, psoas contraction, acute or increasing abscess, loss of power, pain, night-cries, grunting respiration, inclination to lean on chairs, etc., or any other suggestion by face, attitude, or gait that the proper degree of support has not been secured. For the fulfilment of all the indications a wheeled couch is recommended, consisting of a canvas support laced to an iron frame, which is adjustable at any convenient height or incline. The canvas is provided with the necessary aperture, closed by a flap. Straps, pads, and weights are added for support, fixation, and traction.

Adjustable pressure to antagonize the kyphotic projection is produced by means of straps. The patient need rarely be moved for any purpose whatever. When acute symptoms have been absent for several months the patient may gradually and tentatively be allowed greater liberty under the protection of a brace carefully adapted to the needs of the case.

Tapping the Lateral Ventricles of the Brain was the title of a paper by JACOB FRANK, M.D., of Chicago, Ill. There should be no hesitation in tapping the ventricles wherever it is indicated. In tubercular meningitis it is the effusion and not the deposit of tubercles that causes danger and death.

One case in point was that of a patient suffering from paralysis, loss of sensation and convulsions, and a diagnosis of tumor of the upper fissure of Rolando had been made. No tumor was found, but on tapping the ventricle three or more ounces of fluid escaped, giving immediate relief to the patient of all symptoms, none of which have since returned.

Method of Reaching the Ventricles.—In a general way, after the skull has been opened, it is not a difficult matter to puncture the ventricles from any portion of the cerebral cortex. From my own experience, by incising the membranes I can make digital examination much better.

Instrument Used.—I prefer to use a cannula with a blunt stylet, as being less likely to wound any arteries.

Shall Drainage be Free and Rapid, or Slow?—This must be decided in each individual case. If it is an inflammation in retrogression, tapping and removing the fluid without drainage is best. If there is an abscess of the brain which has broken into the ventricle, rapid evacuation and drainage is best and safest.

Indications for Tapping.—Among the most urgent are effusion of blood into the ventricles from trauma or disease, abscess involving the ventricles, chronic hydrocephalus without enlargement of the head; with enlargement of the head it is likely to lead to fatal results.

In discussing Dr. Frank's paper, DR. GRAHAM, of Chicago, said, in all cases of traumatism and inflammation with one sided paralysis, tapping should be done, and if we have or suspect abscess, the case is not properly investigated unless we have explored the ventricular cavity.

PROFESSOR LAVISTA, of the City of Mexico, said that he fully agreed with Dr. Frank, but instead of simply trephining he would perform craniectomy, which was more conducive to a final permanent cure than tapping alone.

Some Points in the Surgical Treatment of Appendicitis was the title of a paper by AUGUSTUS P. CLARKE, A.M., M.D., of Cambridge, Mass. In every case in which there is reason to believe that the vermiform appendix is involved, though the symptoms at first may be mild or transient, the surgeon or medical attendant should be ready to institute measures against the occurrences of sudden surprises and unusual results. There is great probability in almost any event that the appendix, during an attack of inflammation, will become adherent to other parts in the immediate vicinity. In many cases, if not in the most, incision should be made over the point of greatest tenderness; this corresponds to the McBurney point. A liberal incision, when timely, made over the tender part, has always yielded, in the cases occurring in the author's practice, an immediate and permanent result. In all cases after the incision has been made the parts should be thoroughly explored; if the appendix is within easy reach it should be brought forward and then sewed off by means of sutures of aseptic kangaroo tendon. The cordwainer's stitch will be most convenient for accomplishing this. If, however, the appendix is bound down by firm adhesions, or if it cannot be found without much difficulty or without doing excessive violence to the cæcum or to other parts, it will be far better to allow it to remain, for its presence, when thus left, will not seriously interfere with the patient's recovery. In most cases when the mesentery or other parts have been sufficiently detached the appendix should not be tied but should be clamped, and then sewed off by means of carbolized animal sutures; as soon as all hemorrhage has been controlled the appendix may be incised about two centimetres from the cæcal tissue. In order to prevent adhesions of the stump or base of the pedicle to other structures the peritoneal tissue in immediate vicinity of the margin of the incision should be closely approximated by a subperitoneal suture. The smaller sized kangaroo tendon, rendered aseptic, should preferably be the material for such use.

The danger of the subsequent occurrence of hernia may

be overcome by paying strict attention to the closure of the severed layers that have been divided in the operation; the peritoneum, the muscular tissue, the fascia, and the external integument should each be brought together separately. Carbolized animal sutures should be used for this purpose. Entire closure of the wound by the first intention can be effected only in those cases in which the operation has been undertaken in the early stage of the attack. After the formation of an abscess complete union at first cannot be expected to follow, because some method for facilitating drainage for a while will have to be employed. Trendelenburg's posture in this, as in all cases of abdominal section for intestinal affections, cannot be overestimated. In every such case of abdominal section when a drainage-tube has been employed, the possibility of the occurrence of hernia should not be overlooked. In all cases, whether the drainage-tube has been required or not, a firm binder or a thorough bandaging should be employed; the patient for some weeks should be kept for the most part in the horizontal position. The question often arises: Should the surgeon, when called upon in the later stages of a case, advise operative interference? In answer to this, it may be remarked that our experience in such cases is favorable to the adoption of an exploratory incision. When an operation is undertaken in the later stages, the patient must, of course, assume more risks, for the chances of recovery are much less than when an operation is attempted much earlier, though surgical measures at such late date may prevent the rupturing of an abscess into the peritoneal cavity; when there has been such a rupture, removal of the pus and cleansing of the parts may afford an opportunity for a retrograde process of the disease to take place. Nothing, therefore, but the occurrence of extreme collapse should weigh against the employment of operative measures. In those cases of appendicitis which have gone on to suppuration before operative measures have been undertaken, there may occur secondary abscess in other portions of the abdominal cavity. An operation to insure relief must therefore embrace a course of procedure which will afford a free discharge to all accumulation of purulent exudation; it will sometimes be necessary to make a prolonged dissection at different parts and also to overcome adhesions of an unusual extent. Great care will also have to be exercised lest an opening be made into an adherent intestinal mass. In some instances portions of the epiploon may have become gangrenous; there may occur in the veins of the abdomen an inflammation that may extend outward to the other vascular tissue. In carrying out, for these complications, the necessary surgical treatment, much judgment will have to be exercised, and much precaution taken that the dissection or search be not prolonged beyond what may afterward prove to be a beneficial or safe proceeding.

SECTION ON GENERAL MEDICINE.

First Day, Tuesday, September 5th.

Victor C. Vaughn, M.D., of Ann Arbor, Mich., President, in the Chair.

The Principles of Immunity and Cure in the Infectious Diseases was the subject of the President's address. He said that he wished to present a theory of the immunity of the infections. Theories benefit chiefly by their suggestiveness. A theory must not be valued entirely by its truth, but its use in leading to results must also be considered. Immunity may be natural or acquired. For example, the domestic fowl is not susceptible to anthrax, but the fowl may be rendered susceptible; still the immunity is natural. The child is susceptible to diphtheria; the adult takes it with difficulty. Dr. Vaughn believes that immunity is inherent in the parent cell. The difference in immunity is in the person, not in the anthrax. The germ is the same, but the adult immunity is due to the attained cell activity. Dr. Vaughn believes that immunity is a question of cells, not of chemistry. Ehrlich believed immunity wholly humoral. This view must be modified. The transmission of immunity from the father to the child must be cellular. The head of the spermatozoa is fused with the cell of the ovum. There is a quantitative relation between cause and effect in the production of immunity. A man may have small-pox a second time if the exposure be very virulent or the man's health is much below par. The immunity produced by a germ is greater than that produced by a vaccine. A third method is by sterilized cultures. What constituent of the sterilized culture gives the immunity? All will agree that it is not the ptomaïne.

The theory of antitoxins is very convenient. This is not the same as the killing of certain germs by their own productions. It is, however, as if we should find in nux vomica an antagonist to strychnine.

The immunizing substance is in the germ itself. Artificial immunity has not been obtained except by the injection of the germ itself in its own cell-wall or in solution. The same effects have been obtained by the bodies of bacteria or live bacteria modified.

Dr. Vaughn insists that the immunizing substance is part of the germ itself. It is not a split product, but the essential characteristic part of the cell. The three methods of immunity are in principle the same: 1, by an attack of the disease; 2, vaccination; 3, sterilized cultures.

The immunity is due to some part of the cell or something produced by the cell. What organs of the body are effectual we do not know, but probably the cell producing glands. The spleen, the bone marrow, the thymus and thyroid glands are probably the ones. They are the organs of the nucleated white blood cells which contain larger and more numerous nuclei than any other tissue in the body. It is, Dr Vaughn believes, the nuclei that is effective. He has tried to prepare this substance in its active form from compressed yeast and from brewers' yeast, but finally succeeded by using pure cultures of yeast.

Dr. Vaughn has demonstrated the truth of his theory by experiment. Yeast nuclein has marked germicidal effects. Five cubic centimetres of salt solution inoculated with the staphylococcus pyogenes aureus was found to contain many germs, but after two hours they were all dead. Experiments on guinea-pigs (with control animals) showed that tuberculous sputum was rendered innocuous. A 1 to 2,700 solution destroyed germs. The solutions keep well, and proteid materials are preserved by a minute quantity of nuclein.

Dr. Vaughn seems to have discovered an internal antiseptic which will kill germs without injuring patients. There is no chemical substance that will do this. The nuclein therapy does not call for minute doses. We may hope for great results, but if this fails we must seek farther in a like direction.

Forms of Malaria and their Characteristic Features was the title of a paper by Dr. Francisco A. Risquez. Caracas, Venezuela. He said the malarial diseases in Venezuela may be classified as follows: 1. Intermittent forms, generally quotidian, occasionally tertian. 2. Continued forms, including the varieties *a*, bilious, *b*, icterohematuric. 3. Pernicious forms, including the varieties *a*, pernicious proper. *b*, complicated. 4. Larved forms, including the varieties *a*, periodic, *b*, continued.

The forms of the first group are easily recognized by the features of the paroxysm and by the periodic element. When the access is prolonged, the diagnosis may be difficult. The forms of the second group are distinguished by the gastro-hepatic symptoms and the indications of the urine. They may be confounded with others, especially the yellow fever, and the distinction becomes often a matter of life and death. The forms of the third group are recognized by the pre-existence of malarial paroxysms. It may become almost impossible, however, to distinguish between cholera, pneumonia, or tetanus and cases of choleriform, dysenteric, tetanic, etc., pernicious fevers. The forms of the fourth group present still greater difficulties, especially in the continued varieties. They may

assume all the appearances of typhoid fever, of cholera, of dysentery, of paralysis, of hemorrhage. The malarial cachexia may simulate tuberculosis, hepatic abscess, etc.

An early diagnosis is indispensable in these cases, because they require the fearless administration of quinine; and this drug may be contra indicated in the non-paludal diseases. There is but one unquestionable method of diagnosis: the microscopic examination of the blood. All malarial manifestations are accompanied with melanœmia; melanœmia presents itself exclusively in malaria, the sign is, therefore, pathognomonic. A drop of malarial blood, under the microscope, shows the masses of black pigment in the plasma. The manipulation requires no special technique; it is simpler than the examination of the urine. It does not require, as the parasite of Laveran does, an investigation by an expert with high powers. Our method requires only a few slides and covers, and a drop of blood obtained from the finger, previously washed. The preparation is taken to the laboratory and there examined. The strong mineral acids may be used as reagents. A search after pigment should be made in all suspected cases. The number and size of the pigment masses is proportional with the degree of malarial poisoning. If they are found at all, quinine should be given. I have found pigment in all forms of malaria. I have found it also in other diseases, but only as an evidence of malarial complication. Melanœmia is always an indication for the administration of quinine. The life of the patient depends often in these cases upon a prompt diagnosis.

Dr. David Cerno and Dr. Cronyan, of Buffalo, discussed this paper.

The third paper was read by Dr. Mendezabal, of Orizaba, Mexico, on "Paludal Fever in Orizaba." This was a complete exposition of the subject and occupied the latter half of the session.

Second Day, Wednesday, September 6th.

An Outbreak of Typhoid Fever Presenting Unusual Features.—Paper by Dr. William C. Dabney, of Virginia. This paper was based on a study of fourteen cases of continued fever occurring at the University of Virginia between January 15 and April 1, 1893. The epidemic, or outbreak, presented the following features of interest: 1. There had been no typhoid fever in or around the University, so far as I could learn, for several months. 2. Between the middle of January and the first of April, 1893, there occurred fourteen cases of continued fever among persons living or employed on the University grounds. 3. The persons who had this continued fever had rooms at widely separated parts of the University grounds, but all took their meals at the same hotel. 4. The water supply of this hotel was the same as that of the other hotels and of other parts of the University, and the sanitary condition of the building was good. 5. A part of the milk supply was obtained from cows whose teats had been washed in water contaminated by sewage and probably infected with typhoid-fever germs. It was in evidence also that at least five of the fourteen persons used milk at every meal. 6. Of the fourteen cases of continued fever, five presented the typical features of typhoid; seven were typical in character; and of the other two I cannot speak with certainty, as they were not under my care and I could get no satisfactory history of the cases.

This paper was discussed by Dr. Ashton, of Dallas, Texas, who confirmed the views expressed by the author.

Dr. Claiborne, of Virginia, said that he found the diagnosis between typhoid and malarial fever difficult. He is in the habit of testing such cases by giving quinine, gr. xx., three times a day.

Dr. Larabee, of Kentucky, reported thirty-seven cases of typhoid due to washing milk-cans with sewage-infected water. He agreed with Dr. Claiborne in the diagnosis by quinine. He considered the term "typho-malaria" a disastrous error. He believes that the intestinal lesions will be found in all atypical cases of typhoid. When diagnosis has once been established, the sooner quinine is abandoned the better.

Dr. Cohen, of Pennsylvania, asked why mixed infection was not possible. He also stated that atypical cases of typhoid were very common in Philadelphia. He uses quinine hypodermatically to establish the diagnosis.

Dr. Leighton, of Brooklyn, N. Y., reiterated the opinion of Dr. Claiborne.

Dr. Sibney, of Pennsylvania, reported forty cases in an orphan asylum.

Dr. West, of Galveston, Texas, said: "The 'typhoid condition,' so called, has led to confusion because it is not found in most cases of typhoid." He believed quinine a reliable test drug to eliminate the diagnosis of malaria. He had never seen a true case of mixed infection. He believed they do occur, but are very rare.

Dr. Wilcox, of South Carolina, said that he had used quinine hypodermatically for diagnosis.

Dr. Andus, of Pennsylvania, agreed with the latter.

Dr. Parsell, of Illinois, emphasized the importance of treating doubtful cases with great caution, as perforation is liable to occur.

Dr. Vaughn, the Chairman, said that typho malarial fever had never been demonstrated by examination of the blood for malarial germs and the finding of the lesions of typhoid fever in the intestines. There are three theories of typhoid—1. As due to a single germ and no other. 2. That it is a modified form of the bacillus communis coli which sets it up. This is the French theory, and so it is possible for any fecal infected water to cause it. 3. Dr. Vaughn's own theory: it may be caused by any one of a number of germs, which differ—hence the different types. In an experience of many thousand cases, he had never seen a typical case of typhoid as described in the text-books. He had never found the typical German germ. In a recent outbreak he had found a similar germ in the drinking-water and in the spleens of the victims, but the germ was not the typical typhoid germ as described by the Germans. He believed that typhoid might be due to many different germs. It is a mistake to try to divide diseases by too sharp lines.

Most of us under ordinary circumstances are immune from typhoid. He believed that a healthy person might carry the infection without himself developing the disease.

Dr. Dabney closed the discussion.

A Contribution to the Clinical Study of Prolonged Remittent Fever.—The second paper with this title was read by Dr. David Lobo, of Caracas, Venezuela. He said that it was his purpose to describe a certain form of malarial infection, which, he believed, has received very little attention from standard writers on tropical diseases. The description was based on clinics exclusively, referred to the various individual conditions, and was intended to impart his personal views in regard to the malady as it occurs at Caracas. The normal type of malarial fever, the intermittent form, is rarely met with in said city, and its presence, when noticed, can generally be traced to an original exception at some of the genuine sources of the infection. Close examination will seldom succeed in detecting any marked congestion of the liver and spleen in cases developing within the bounds of the city. This congestion cannot, therefore, be regarded as a characteristic manifestation of the fever under consideration. The aspect and extraordinary course of the pyrexia are probably due to corresponding variations in the power and quality of Laveran's corpuscles, to over-poisoning of the blood, or to some distinct element operating simultaneously with the paludal germ. Investigations in this direction have not as yet been made.

Temperature.—Variations in temperature do not respond to any fixed law of recurrence. It generally ranges from 38.5° to 40.5° C., and drops or rises unexpectedly. Remissions take place at any moment of the day. Intermissions may recur, but they never should be

trusted. Chills and sweating may be observed, but never as definite stages of the fever.

Special Symptoms.—Circulation and respiration do not exhibit any deviations, except those induced by the reaction of the organism under the influence of abnormal heat. Divergencies between pulse or respiration and temperature should be looked to and carefully treated. Digestion: Appetite either very poor or absent. Tongue smooth, clean and moist. Bowels generally act well, but diarrhœa or constipation is sometimes present. Intense abdominal pain, meteorism, profuse diarrhœa, and obstinate constipation are indicative of some complication located in the intestines. Vomiting may occur, but it is never distressing. Urine offers no change worth mentioning. The excretion of albumin or blood is never observed. Liver and spleen: In respect to these organs, reference is made to the preliminary considerations contained in this abstract. But he desired to lay particular stress on the fact that the spleen is seldom enlarged or congested in long remittent fever. Nervous system: Headache and vertigo are not common symptoms. Delirium is never present. There is no impairment of sensibility and mobility.

Course, Duration.—The fever frequently runs its entire course free from complications. There are serious incidents, generally; their gravity depends on the importance of the organ attacked. Defervescence takes place, either gradually or by crisis. The former process is more common. As regards duration, remittent fever is not governed by any cyclic law, as typhoid or yellow fever are wont to be. The briefest term ranges from fifteen to twenty days; the longest extends to three months, seldom more. The average duration can be estimated at thirty-five days. It is obvious, from the preceding description, that the whole clinical history of the disease may be condensed into two prominent facts, viz., an irregular temperature and a long, weary course.

Diagnosis.—The main points by which long remittent fever can be discriminated from other malarial forms, are its uncommon course, its irregular temperature, the absence of marked stages and of hepatic or splenic troubles, and its resistance to quinine. Between it and typhoid, there is no possible confusion; typhoid is cyclic in its career, is accompanied by intestinal lesions, presents peculiar eruptions, and is extremely rare at Caracas. The so-called typho-malarial fever exhibits typhoid symptoms, which are never present in ordinary remittent. Vomiting of black matter and albuminuria are perfectly distinctive of yellow fever. The course of this never exceeds ten days. Pernicious fevers are sufficiently distinguished by their short duration and characteristic aspect.

Prognosis.—Where complicating or intercurring processes do not occur, a fatal issue is seldom to be feared. High temperature, extreme weakness, frequent vomiting, copious sweating, and diarrhœa, generally impart a serious character to the disease. Prognosis is entirely different when we have to deal with organic complications. In order of gravity, cerebral disorders rank first, and are followed by pulmonary congestion, entero-colitis with watery discharges, intestinal ulceration, and peritonitis. Congestion of the liver recedes under proper treatment. Measles, as an accident, occurred in one of my cases; this is the only intercurring disease I have ever observed.

Complications.—The fever may give rise to a special inflammation of the lung, to which the term pseudo-pneumonia can be properly assigned. Crepitant râles are seldom heard. Tube respiration is an early sign. Sputa are viscid, scanty, and bloody, but seldom rusty. Pain is generally absent. The seat of the fluxion is subject to frequent change. The pleuræ are sometimes included in the process. Among nervous complications, none is so terrible as cerebral congestion. It may assume a convulsive or a comatose form, but the latter is more common. The convulsive form is probably due to meningeal congestion. The issue is fatal in nine cases out of ten. Encephalitis, localized lesions, and spinal derangements I have never seen to complicate the fever. Hepatic congestion is also a possible occurrence, but is not necessarily connected with the disease. It yields speedily to remedial agents. Abscess of the liver is very rare.

Acute entero colitis, dysentery, and choleriform diarrhœa are fearful complications, as they often lead to fatal results. Hemorrhage and acute peritonitis are apt to occur as secondary phenomena, subsequently to ulceration of the digestive tract.

Treatment.—These cases are slowly influenced by quinine. Warburg's tincture is a valuable remedy. Cold baths or lotions to lower the temperature, and a generous diet, are indicated.

Afternoon Session.

In the afternoon Dr. Osler opened the discussion of Dr. Lobo's paper. The belief is now universal that there exist in all types certain organisms, the plasmodia. They are diagnostic. We lack the evidence of culture outside of the body and of inoculation.

Dr. Osler said that he would not like to criticise Dr. Lobo's paper without experience in his country, but that in the absence of blood studies he would not feel certain that he might not have met with cases of typhoid fever. Dr. Osler said Dr. Resquez emphasized the value of blood pigment in diagnosis, but this is present in very small amounts in some very severe cases.

Dr. W. A. Thayer, of Baltimore, said that the common type of malaria in Baltimore was quotidian, though the tertian type was frequent. The tertian type is characterized by an organism the same as in other countries, an amœboid body which undergoes the changes which have been so often described. Segmentation of the organism always precedes a paroxysm. The flagellate bodies are sometimes seen. The quartian organism is like the tertian, but breaks into fewer segments. The organism in the fall type is entirely different. It has a ring-like appearance and it is smaller than the others, and has very few or even no pigment bodies. The segmenting bodies are not seen. The pigmented crescent is the most characteristic organism of the fall type of intermittent. They do not usually appear till after ten days. They do not appear in the tertian or quartian form.

Dr. Lobo said that the clinical appearance of his cases was so different from typhoid that he was positive that they were not cases of typhoid. He did not think that any comparison was possible. Typhoid was almost absent in Caracas. He had seen typhoid cases there, but very few.

Vaso-motor Ataxia.—The first paper of the afternoon session was read by Dr. Solis-Cohen, of Philadelphia, on this subject. He said may persons exposed to cold and wet will develop many different forms of disease. This is called idiosyncrasy. He called attention to a circulatory idiosyncrasy. He called it vaso-motor ataxia, because either paresis or spasm might be present. The most striking instances are seen in peripheral vessels. The cause is central. Graves's disease and Raynaud's disease are familiar.

He made the following points: 1. By the term vaso-motor ataxia it is proposed to designate the condition of inability of the mechanism of circulation present in certain persons, and characterized by abnormal readiness of disturbance, with tardiness of restoration of the equilibrium of the cardio-vascular apparatus. The manifestations are most strikingly displayed in the terminal vessels, and occur chiefly under the action of external influences, especially cold; of toxic agents; and of emotion. The stimulus may be applied centrally or peripherally, but in each case the resulting phenomena indicate a defect of central inhibition.

2. Vaso-motor ataxia is in many cases congenital; in some inherited; the condition is not rarely present in several members of a family.

3. In some cases the phenomena are of paretic, in others of spasmodic character. Usually the two kinds of phenomena are displayed in varying degree in the same patient. Whether spasmodic or paretic the symptoms are suggestive of inco-ordination.

4. In exophthalmic goitre, especially such cases as are produced by emotion or are markedly intermittent, is found the extreme type of the paretic variety of vaso-motor ataxia.

5. The form of Raynaud's disease known as "local syncope" furnishes an extreme type of the spasmodic variety; while "local asphyxia" exhibits spasmodic and paretic phenomena.

6. Between these extremes are numberless gradations down to the slightest departure from normality; while even the extreme symptom groups represent merely exaggerations of phenomena that under certain conditions occur in normal individuals.

7. Dermographism is an essential feature of vaso-motor ataxia, and in most cases factitious urticaria can be readily produced by cold or by pressure, or by both; mottlings of the skin, certain peculiar markings of the nails, teleangiectases, and stigmata are common.

8. There is usually a hemorrhagic tendency, as shown by ecchymoses, petechiæ, epistaxis, hæmoptysis, hæmatemesis, hæmaturia, and retinal hemorrhage.

9. Even in the absence of hæmaturia red blood-cells are often found in the urine; uric acid, urates, and oxalates are likewise common; the presence of albumin, tube-casts, and cylindroids is less common, and is usually intermittent. Glycosuria has been observed.

10. In many striking cases there has appeared to be morbid alteration of the thyroid gland.

11. The action of the heart is usually rapid, irregular, and easily disturbed. Palpitation is common, and in some cases intermittent tachycardia has been noticed. Hæmic and functional murmurs are not uncommon.

12. Among other symptoms and morbid associations observed are drug idiosyncrasies, urticaria, local œdema, angina pectoris and pseudo angina, hyperidrosis, asthma, hay fever, vertigo, migraine and other forms of headache, transient hemiopia and other visual disturbances, persistent mydriasis, astigmatism, myopia, hyperopia, menstrual irregularities, intermittent polyuria, rheumatism, chorea, epilepsy, neurasthenia, gastralgia, enteralgia, and membraneous enteritis, most of which are doubtless related as effects of a common cause, or as secondary results.

13. The development of pulmonary tuberculosis in some cases is probably a sequence of vascular and trophic disturbance in the lung.

Dr. H. A. West opened the discussion. He said that the vaso motor ataxia as described by Dr. Cohen would explain many phenomena observed by the general practitioner.

He said that it threw light on many of his own cases, which he had not previously understood. He considered the name exceedingly happy.

Dr. Carmona Y. Valle, of Venezuela, spoke of the importance of this subject to the proper understanding of many cases.

The Course, Results, and Complications of Erysipelas.—Dr. J. M. Anders, of Pennsylvania, read the paper.

The author gave elaborate statistics to prove that debilitating diseases predispose to the disease. Complications are common, but acute articular rheumatism is notice ably so. It is only exceeded in frequency by abscess as a complication.

Dr. J. Cronvan, of Buffalo, N. Y., reported a case of progressive locomotor ataxia which recovered after having an attack of erysipelas. He said that he had no doubt of the antagonism of erysipelas to certain other diseases.

Dr. Desaussure, of Charleston, N. C., asked if the abscesses were in the cellular tissue or were they in the lymphatic glands.

Dr. Anders closed the discussion.

SECTION IN LARYNGOLOGY AND RHINOLOGY.

First Day, Tuesday, September 5th.

E Fletcher Ingalls, M.D., of Chicago, President, in the Chair; English Secretary, T. Murray, M.D., of Washington, D.C; Spanish Secretary, Angel Gaviño, M.D., of City of Mexico.

The Chairman, in opening the section, commented upon the large amount of work which American laryngologists had been called upon to do at the various societies during the last few months, and upon the growth of this specialty in the United States, where there were now probably five hundred men fairly competent to treat nose and throat lesions. He believed that the building of the pan-American railroad would do much to develop certain of the southern countries as climatic resorts during the winter months.

Some Forms of Nasal Reflexes, with Report of Cases.—This was the title of a paper read by Dr. S. K. Merrick, of Baltimore, Md. He reviewed the history of nasal reflexes from the original suggestions of Voltolini down to the present time. The principal ones insisted upon by various writers were ocular disturbances, cough, cardiac and gastric manifestations, chorea, epilepsy, with various forms of headache.

McBride, of Edinburgh, has raised the question, "whether the cure of the local condition within the nose or the counter-irritant action of the application controls the reflex." Bosworth cites Bourchard, as quoted by Rualt (in support of the counter-irritant action), who cured a case of sciatica by cauterizing the lobe of the ear. The question of "moral effect" has very naturally been invoked to explain many of these cures, yet I believe, that while it may have some force, it is secondary in most cases, but may be, I think, the chief factor in a small per cent. of cases. The cure of intra-nasal disease is responsible, undoubtedly, for most of the successful results.

There are, then, three chief views held as to just how these reflexes are cured, viz.: 1, By cure of intra-nasal disease; 2, by counter-irritation; 3, by moral effect.

None of these is wholly true or entirely false, as the following cases verified:

Cases I. and II. showed that reflex eye troubles were relieved, not suddenly, but when the local intra-nasal condition was cured.

Case III.—a case of reflex headache and vertigo—was relieved by the counter irritant action of the cautery before the local disease of nose was favorably affected.

Case IV.—a case of sciatica, cured almost immediately on cauterization of the turbinates—was doubtless relieved by the "moral effect."

Reflex Epilepsy from Intra-nasal Disease was the title of a paper read by Dr. John O. Roe, of Rochester, N. Y. He concluded:

1. That epilepsy is a frequent result of peripheral irritation, which may be excited by a local disturbance affecting the peripheral nerves in any portion of the body. 2. That the susceptibility to peripheral irritation varies greatly in different persons, as is shown by the fact that irritation of the same kind or degree will not always cause the same amount of central disturbance, or may develop reflex disturbance of an entirely different character. 3. That the nose is frequently the seat of sufficient irritation to excite a variety of reflex manifestations; that these disturbances may be confined to the brain centres, manifested in epileptic convulsions, or they may be reflected to other peripheral organs, giving rise to manifestations of an entirely different character. 4. That in the nose there are well-defined sensitive areas, which are more readily stimulated by diseased conditions or by irritants introduced from without, than other portions of the nasal cavity. 5. That these areas are rendered inordinately sensitive to irritation by abnormal conditions in the nose, frequently independent of "neurotic habit." 6. That the undue susceptibility of these sensitive areas and the production of reflected disturbances—and especially those of epilepsy—is more often excited by intra-nasal pressure

than by any other local condition. 7. That the frequency with which epilepsy has been found to result from intra-nasal disease emphasizes the importance of interrogating the nose in all cases of epilepsy, and especially in those in which the cause is in any manner obscure.

Dr. Price Brown, of Toronto, Canada, had never seen true epilepsy result from intra nasal disease, but had seen the latter produce many neurotic symptoms which without relief to the exciting cause might have eventuated in epileptoid seizures. He narrated cases illustrative of eye trouble and hay fever, both permanently relieved by the removal of intra nasal pressure.

Dr. S. Solis-Cohen, of Philadelphia, opposed the extreme position taken by many rhinologists in this matter of nasal reflexes. He was inclined to doubt the existence solely of a neurotic substratum in these cases. Frequently there were evidences of instability in the circulatory mechanism. In such patients various peripheral excitants might cause epileptic disturbances. In such cases we should note carefully the condition of cardiac action. It was frequently disturbed by trivial causes, which in a healthy person would produce no effect. Furthermore, we frequently saw dermographism or factitious urticaria. This was brought out by tracing a probe over the tense skin, using light pressure, occasionally heavier pressure was necessary, and at times the subsequent application of cold over the tracings. After a while the design traced would stand out in bright red lines on the skin, or wheals would appear in the track of the probe.

Of course the question of "moral effect" does undoubtedly play an important part. There was again a class of cases with intra-nasal obstruction, producing a sense of pressure at the root of the nose, and also over the supra- and infra orbital regions. He had for this condition obtained good results from the use of quinine hydrobromate in dosage of from fifteen to thirty grains given four to six hours before the paroxysm of pain was due. He usually combined it with ergot to obviate unpleasant ear symptoms.

Dr. A. W. de Rhoaldes, of New Orleans, La., related the history of a case recently seen by him. A strong, buxom, country girl complained of slight deafness. There was nasal obstruction on the left side which was removed by the saw under cocaine anæsthesia. Very quickly there supervened supra-orbital headache, embarrassed respiration, paleness, and rapid and feeble pulse. A short expiratory cough came on and lasted three days, relief only resulting from the hypodermatic use of morphia, and then but partially. When the nostril was dressed the same symptoms recurred, lasting one week. A third dressing resulted likewise. The symptoms were at first thought to be due to the cocaine, considerable of which had been used during the operation, but none was used during the dressings, and that idea had to be given up. The nostril was left alone and complete healing resulted with relief of cough. He thought that where the so-called reflex effect is at a distance from the seat of lesion, the patients were generally of a distinctly neurotic character.

Dr. J. C. Cobb, of Boston, doubted the permanency of the cure in many of these cases. He had seen asthmatics relapse after a year of freedom from symptoms. There is often an effect produced which is a mixture of suggestion and true physiological relief.

Dr. Herrick added, in the discussion, that any drug which controlled the circulation will help these cases. Quinine undoubtedly has such an effect. This fact does not, however, negative the idea of reflex action.

Alumnol in Diseases of the Nose and Throat.—Dr. J. Mount Bleyer read a paper with this title. He gave a history of synthetic chemistry leading up to the use of many of the newer compounds. He had found alumnol antiseptic and astringent. The salts of aluminium, particularly the acetate and the aceto tartrate, had been long used. The new preparation was a white powder, soluble in cold water up to a strength of forty per cent. Solutions turned dark on exposure to the air, but this change of color did not seem to interfere with their efficiency. It precipitated albumin, but the precipitate was redissolved in an excess of the alumnol. He had used the remedy in epistaxis, for naso-pharyngeal hemorrhage after removal of adenoids, and for cleansing the nose and throat in various diseased conditions. In mucous plaques of the tongue it had been especially beneficial, proving superior to chromic acid.

Dr. Bleyer also exhibited an apparatus for detecting lost intubation tubes after operation. In one case recently seen, he had attempted to remove the tube but found it missing. He judged it was in the trachea, which was congenitally misshapen. There was no respiratory difficulty. The apparatus consisted of two parallel needles connected with an ordinary induction coil. These needles were thrust between the tracheal rings, and when they impinged upon the tube the electric circuit was closed and the alarm set off.

In discussing the matter of alumnol, Dr. D. Bryson Delavan, of New York City, said that its use had given him satisfaction, though he could not extol it as highly as the reader of the paper had done. One objection to its use was its cost, which in this country was four times as great as in Germany.

The Treatment of Certain Cases of Chronic Laryngitis was the title of a paper presented by Dr. Angel Garviño, of the City of Mexico. He alluded to those cases in which symptoms persisted though the objective examination revealed nothing abnormal, and where no tuberculosis would be suspected. He makes it a routine practice to examine the secretions of the larynx in every case, and when the mucous membrane is apparently normal he scrapes it and examines the scrapings. In both secretions and scrapings he has found the tubercle bacillus.

The regions thus operated upon have been the arytenoids, false cords, ventricular bands, and epiglottis.

For treatment, he recommended the use of intra-laryngeal injections of some oily menstruum impregnated with creosote, salol, or salicylate of bismuth. He also employed bichloride and zinc applications and gave creosote internally.

Second Day, Wednesday, September 5th—Morning Session.

Dr. A. W. de Rhoaldes, of New Orleans, read a paper on "An Improved Motor Dynamo and Electrical Cabinet for the Adaptation of the Street Current to Office Work."

The paper was a highly technical description of a new apparatus he had devised, and was illustrated with diagrams.

A Case of Elongation of the Epiglottis, Reduced by Operative Measures, was the title of a paper read by Dr. Price Brown, of Toronto, Canada. His patient was a young woman, aged twenty-three, with a tuberculous family history, and of a doubtful pulmonary condition herself. She had always been subject to frequent colds, always attended by hoarseness, and at times complete aphonia for several days. Great difficulty had been experienced in freeing the throat from mucus. What could be seen of the larynx appeared perfectly healthy. The epiglottis, however, which was long and narrow, with the end turned up, lay in a horizontal position, the whole of the free end pressing against the posterior wall of the pharynx, during ordinary respiration the air passing up and down through the open sides. At forcible respiration the epiglottis was varied slightly, seemingly enough to admit the passage of a knife-blade. The whole of the larynx was deeply seated and the vocal cords quite invisible. It required two and a quarter inches, from the right angle of a probe, to reach the tip of the epiglottis. As the patient was tractable, and a good view of the parts could be obtained, the case was considered a good one for operation, always using a fif-

teen per cent solution of cocaine. On March 1st, the first tentative touch with the galvano cautery was made. There was but slight reaction. On March 4th, during forcible breathing, the galvano-cautery blade was slipped between the epiglottis and post-pharyngeal wall. Then drawing the former forward so as to free the latter, the central portion and left side of the tip were cauterized. The operation was followed by limited sloughing and acute congestion of a mild type. There were two subsequent cauterizations, one on the 18th and the other on the 29th, and the patient was allowed to return home. Throughout the treatment albolene sprays were used to the throat several times a day.

The shortening of the epiglottis amounted to about one-fourth inch; and there was a perpetual niche of one-eighth inch. As there was, however, still a protruding corner, she came back for treatment on June 6th. The epiglottis had entirely healed, and there was no hoarseness. The remaining projections were twice touched with the galvano-cautery, at three-days intervals. In ten days the patient returned home. The sloughs had come away. The epiglottis was regular in outline and uniform in length. The cords could be seen for the first time.

The paper was discussed by Dr. E. Fletcher Ingalls, of Chicago, Ill.

The Easiest and Most Practical Means of Making Galvano-cauterization, Especially to Turbinate Hypertrophies.—The paper was read by Dr. Arthur G. Hobbs, of Atlanta, Ga., and consisted of a description of a small apparatus contained in a rosewood box eight inches long, four inches wide, and four inches deep, and is secured to the wall at a convenient distance from the operator's chair. The wires from an alternating current of fifty-two volts, the most generally used circuit, particularly in the medium and smaller-sized cities, are brought into the operating-room from the street and attached to one end of this little box. The conducting wires are similarly attached to the other end. The apparatus is now ready for the cautery operation and, more than this, it remains always and ever ready, in no way requiring the attention of the operator at any time. When the proper cautery point is attached, through the handle of the conducting wire, it is necessary only to turn a screw projecting from the nearer service, with the left hand, to use any number of volts, or to raise the cautery point to any degree of heat desired. In short, the little apparatus is simply a gauge for measuring out the exact quantity of electro motor force in the form of heat that may be needed for each particular case. The needle and a very narrow blade are the only cautery points ever used, and in all cases they are made to enter at the most prominent point of the hypertrophied tissue, penetrate to the bone when a white heat is reached, then withdrawn through the same puncture while the point is still hot. In no case is a wholesale destruction of mucous membrane ever produced by applying the flat surface of a blade to the protruding part.

Discussion by Dr. D. Bryson Delavan, of New York City.

Some of the Throat Conditions Observed in Gouty Subjects, was the title of a paper read by Dr. Solomon Solis-Cohen, of Philadelphia, of which the following is an abstract:

The term "gouty subjects," as used in this paper, applies not only to those who have had attacks of acute gout, or those who exhibit the characteristic deposits of chronic gout, but also to the much larger number who suffer with the varied and often obscure symptoms of "lithæmia," with a more or less constant tendency to excess of oxalates, phosphates, urates, and uric acid in the urine. In both classes of patients the upper air-passages are frequently affected; and while the gouty diathesis cannot be affirmed to be the sole cause of the local manifestations, it doubtless acts both as a predisposing and modifying influence. A large number of cases by different observers would have to be recorded in detail and carefully analyzed, before characteristic signs of throat-gout could be laid down. In most, if not in all, cases the condition is a chronic one, with a tendency to paroxysmal exacerbation. Inflammation is not a necessary feature of the case. In the author's experience the most prominent symptoms are sensory. Pain and abnormal sensations are referred to various areas apparently healthy.

Sometimes during a paroxysm these spots show a junction of dilated vessels. There may be a dusky discoloration of the mucous membrane, or an enlarged and reddened follicle. The epiglottis and arytenoid summits are in the larynx the favorite seats of abnormal sensation. In some instances we have a diffuse laryngitis with a "corned beef" appearance. In the pharynx the tonsillar and peri tonsillar structures and the angles of junction of the postero-lateral walls, have seemed to be most frequently affected. Luschka's tonsil may be reddened and tumefied when the rhino pharynx is invaded. Tubal catarrh and gouty changes in the drum membrane may cause subjective noises and peculiar sensations in the ear.

In young patients, the pharynx and larynx are often covered with a grayish tenacious mucus; in those past middle life the pharyngeal membrane is more often dry and pale, exhibiting a network of enlarged and tortuous vessels, or mottled with livid patches. Spasmodic obstruction to nasal respiration, with or without accompanying coryza, spasmodic choking in swallowing, and spasmodic obstruction to voice and to laryngeal or bronchial respiration, have been observed in a few cases. The diagnosis depends on urinalysis and associated symptoms of gout or lithemia. Local treatment must be of the mildest character, and is palliative only; for permanent relief of greater or less degree, dependence must be placed on dietetic, hygienic, and medicinal measures appropriate to the gouty state.

Discussion by Drs. J. E. Logan, of Kansas City, Mo., and John H. Lowman, of Cleveland, O.

Dr. D. Bryson Delavan, of New York, exhibited an electric lamp for giving illumination for office work in nose and throat disease.

(To be continued.)

Methyl Chloride in Neuralgic Affections.—Hertmann (*Therap. Monatsh.*, April, 1893) describes his experience with this remedy, which has been greatly used in France for affections of the nerves, etc. The substance in a liquid state is preserved in iron cylinders resembling siphons, and is allowed to escape from a distance of about half a metre from the affected part, which thereby is cooled to 23° C., and according to intensity of application more or less frozen to some depth. An intense reactive hyperæmia follows, frequently accompanied by blisters, in the course of a few hours. The author gives exact details of treatment in twenty nine cases, comprising fifteen patients with sciatica, five with intercostal neuralgia, the remaining suffering from lumbago, coccygodynia, chronic rheumatism, etc. Twice treatment failed, possibly in one instance—the first experiment—owing to insufficient application, and in the other in consequence of pressure of an abscess on the nerve. The majority were absolutely cured or more or less relieved by each operation, the number of sprayings in each patient averaging two to three. The whole of the affected area should be covered with the white powder which forms on the skin, one spraying often sufficing to produce a cure. The objections hitherto urged are the possibility of erysipelas, lymphangitis, and even gangrene; but the author, among seventy administrations, observed no evil results beyond occasional blistering, not severe in character, and he considers the probability of more serious troubles to be remote, and not more likely to occur than with sinapisms, etc. In order to guard against gangrene, patients suffering from albuminuria and glycosuria might be excluded from this treatment. The author considers that the treatment involves less expenditure of time and money than either faradization or massage, a filled cylinder being sufficient for four to eight sprayings.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, May 22, 1893.

WILLIAM STEVENS, M.D., PRESIDENT, IN THE CHAIR.

Resolutions on the Death of Dr. Lee.—In the absence of Dr. Thomas, chairman of the committee, DR. ROOSA read the resolutions on the death of the President, Dr. Charles Carroll Lee.

The Faradic Current in Gynecology, with Description of Improved Apparatus.—DR. AUGUSTIN H. GOELET read the first paper of the evening, with the above title, and exhibited apparatus.

The apparatus was one which he had presented at the meeting of the American Therapeutic Association in 1891, with improvements. Since that date it had been put upon the market by different dealers. It was adapted not only to gynecology, but to all cases in which the induced current was indicated. In constructing the instrument he had started with certain distinct purposes in view. The long, fine wire gave a current of greater electro motor force and less volume; the short, thick wire gave greater volume and less electro motor force. The instrument presented was so arranged that by switch action a greater or less length of wire could be employed. The long, fine wire, with its high tension and inappreciable volume, was sedative in its influence, but the current had to be appreciable, else it would have no therapeutic effect. It should not, however, be strong enough to be painful. Then the interruptions had to be even in order to produce a sedative effect—three hundred to three hundred and fifty per second in gynecological work. When the interruptions exceeded this the current was inappreciable and inefficient, at least in the vagina. It was passed for sedation ten to twenty minutes, being gradually increased the first four or five to the desired point. Four or five Leclanché cells were used, and the instrument contained a rheostat. He employed the bipolar method in uterine and vaginal treatment, and the relief from pain due to uterine congestion and various other conditions was prompt and efficient. The services of a specialist were not required in treatment by this means. Electrodes were exhibited.

MR. A. E. KENNELLY, of the Edison Laboratory, was invited to make some remarks, and spoke of the instrument, from the electrical, and not from the therapeutical, aspect. He said, with regard to the number of interruptions, it was best to use the natural tone of the instrument, and not to force the rapidity of interruptions beyond that point if one would not break up and cause irregularity of current quality. Speaking of painful or sedative influence, he said that, on making, the current partook of the character of a long wave; and on breaking, of the character of a chop or sharp pitch, the latter being the more unpleasant or painful. He suggested that the more sedative influence of the long, fine wire was due probably to the more uniform and wave-like character of the current, to a wiping out of the jerky, spasmodic elements which were more or less prominent in the short wire.

DR. MARGARET A. CLEAVES did not know of a better nutritive agent in anæmic sensitive patients with pelvic complaints than the abdomino vaginal faradic current. She admired Mr. Kennelly's explanation of the greater sedative effect of the long, fine wire with rapid vibrations, namely, the absorption of the sharp peak of break by the long curve.

DR. A. D ROCKWELL further emphasized the point made in the paper as to the importance of differentiating between the current of tension and that of quantity. Few seemed to fully appreciate their difference physiologically and therapeutically. The current of tension applied to the skin might be very painful, whereas, if applied to the mucous membrane it might be scarcely appreciable; the current of quantity applied to the skin might produce little effect, applied to the mucous membrane it might produce a profound effect. Doctors had lost patients by failing to observe this simple but important point.

DR. GOELET in closing called attention to the difference between connecting the cells in multiple, as was usually done, and in series, and said that two of the four cells in his battery were in multiple, two in series.

Brain of a Pathological Giant.—DR. CHARLES L. DANA presented a brain which he spoke of as the brain of a pathological giant, it being that of the Indian who had died very recently in Bellevue Hospital. The man had been reported to be 8 feet high, and to weigh 350 pounds, but his actual height was 6 feet 7 inches, his weight 300 pounds. He died suddenly, the immediate cause not being known. The brain was a little above the average size, weighing 53 ounces. There was great enlargement of the pituitary gland. Bodily measurements showed the case to be one of acromegaly, and not one of great size from normal growth. This fact was an interesting one, inasmuch as increase in size of the pituitary gland was usually present in acromegaly. It was probable that many cases being exhibited throughout the country as giants, were cases of acromegaly with enlarged pituitary gland.

Note on the Apoplectic Pulse and its Treatment.—DR. CHARLES L. DANA then proceeded to read a brief paper on this subject. The class of cases of apoplexy to which he wished to call attention did not include the most common form, in which the arteries were tortuous and hard, but with pulse of high arterial tension, but certain exceptional ones in which the blood vessels, though tortuous, had become much dilated, non-resilient, the pulse full and of low tension. These patients did not show evidence of much kidney or cardiac disease, although the heart was likely to be moderately dilated and hypertrophied. The apopletic attack was apt to come on suddenly, without warning, during a time of comparatively good health, and was apt to be followed by mental disturbance, vertigo, general weakness of mind and of body out of all proportion to the paralysis or symptoms attributable directly to the seat of hemorrhage. This state, however, varied much in different cases. Improvement took place gradually, but might be interrupted by another attack.

The author had studied the pulse in four such cases, and taken sphygmographic tracings before, during, and after treatment, and had found quite a different condition from that present in ordinary apoplexy with atheromatous arterial walls. The most marked feature was attributable to the want of resiliency in the arteries, the relatively low tension, and the abnormal peripheral resistance. The tracing showed the total area of wave small, the predicrotic notch marked, the dicrotic deep.

The essential trouble in such cases lay in the periphery of the circulatory system, in the capillaries, and was caused by diathetic conditions, as rheumatism, gout, lithæmia, excessive amount of carbonic acid in the blood, etc. The treatment should be based on this view of the cause, and would consist in regulation of the diet, the use of tincture of iron, salicylates, and like drugs, and in this particular class of cases of apoplexy much relief from symptoms attributable to a badly nourished brain often followed the use of cardiac tonics, as digitalis and strophanthus.

In conclusion Dr. Dana expressed the opinion that the sphygmograph was of great value to one who by experience had learned to interpret his special instrument.

Capillary Resistance and the Dicrotic Notch.—DR. ANDREW H. SMITH thought the dependence of the depth of the dicrotic notch upon the capillary resistance could be proven by a simple experiment. Place a ligature about the wrist just sufficiently tight to measurably interfere with the return circulation, and it would be found to exaggerate the dicrotic notch. Give the patient oxygen and the dicrotic notch would become less prominent, showing apparently that when the circulation was arterialized the peripheral resistance was less.

The Condition of the Arteries and Pulse of Great Significance.—Dr. William H. Thomson had long regarded the study of the arteries and pulse as of much diagnostic value. A thorough study of the arterial system should always precede deductions based on the pulse. He had one case at present under observation in which the clinical symptoms were like those described by Dr. Dana, and the pulse was similar. The patient had had several attacks of apoplexy, had a number of tortuous and dilated arteries, and a pulse of low tension. As the author had stated, thickened and tortuous arteries in ordinary apoplexy gave a pulse of high tension. The tracing shown by Dr. Dana was somewhat suggestive of an anacrotic pulse, but the deep dicrotic notch was unquestionably due to a pronounced fall in the arterial current owing to the state of the artery. The practical deduction to be drawn from the valuable paper was, that the arterial change was secondary to trouble in the capillaries and not in the arterioles.

Dr. Mary Putnam-Jacobi thought the special sphygmograph which Dr. Dana had used and praised was faulty in that it was too sensitive and made a tracing, the parts of which were contradictory to the normal tracing produced by the pulse wave.

Dr. Dana said, in closing, that if the tracing shown was contradictory to previous theories, which he did not admit, it was so much the worse for the theories, for the same instrument had shown, repeatedly, markings which were in accord with the pulse tension when varied by the administration at one time of nitro-glycerine, at another of digitalis, etc. The markings were in accord, too, with the studies of the pulse by Broadbent and others.

Dietetics in Diseases of the Stomach.—Dr. Max Einhorn was to have read a paper on this subject, but the limited time permitted of the reading of only a small portion. His subject was divided into three parts: 1, General rules of dietetics in diseases of the stomach; 2, dietetics in acute diseases of the stomach; 3, dietetics in chronic diseases of the stomach.

In his remarks upon chronic diseases of the stomach, the author said the emaciation was due to taking too little food rather than to poisoning of the blood. By appealing to vicarious digestion sufficient food might be given to keep up health and permit the stomach to rest, to receive treatment, and to regain its healthful state. A table of the digestibility of food articles was given. The author's time elapsed while he was speaking of malignant diseases, cicatricial obstruction, etc.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, April 7, 1893.

Charles L. Dana, President, in the Chair.

Case of Myositis Ossificans.—Dr. V. P. Gibney presented the patient.

Dr. Robert Abbe had seen a case, about three years ago, in a man, of large bony plaques in the thigh, involving the quadriceps muscle. No treatment.

Cases of Appendical Abscess of Unusual Germ Origin.—Dr. Robert F. Weir presented the specimens, with histories. He stated that it was well known that a number of other germs than the staphylococcus and streptococcus pyogenes produced purulent inflammation. These were the typhoid bacillus, bacillus prodigiosus, bacillus acidi lactici, micrococcus tenuis, micrococcus tetragenus, and particularly the diplococcus pneumoniæ and the bacillus coli commune. Of these latter two the diplococcus often is present in aural and cerebral diseases of otitic origin, and the bacillus coli commune affects seriously and disastrously the peritoneal surfaces in rapidly advancing septic inflammation. Both of these germs, however, are found wide of the chest and abdomen as the cause of purulent deposits. Besides these we have the saprophytic germs, as the proteus vulgaris, inerabilis and Zenkeri as pus generators. In addition to this, as adding to the interest on this subject, we have recently learned that an innocent germ added to a phlogistic germ augments often the infection or toxicity. He had in two cases been able to detect irregular germ infection by cultures from the pus obtained from abscesses resulting from appendical perforation. In one case the germ found was the bacillus coli commune.

The history of the case is very briefly this:

First attack: Vomiting; temperature, 101½° F.; marked iliac tenderness. Seen by me thirty six hours after. Temperature, 99½° F.; pulse, 128; respiration, 30, shallow; face of bad color; pain, slight; tympanites, marked; tenderness marked at Schüller's line, not much at McBurney's point. Patient cheerful and talkative. Laparotomy advised and performed. Abscess of ʒ iij. turbid pus; appendix, perforated and gangrenous near attachment, removed. Abscess also found running into depths of pelvis; cleaned out and packed. Prognosis unfavorable, as septic conditions were strongly marked. Patient succumbed within twenty-four hours. Autopsy showed general suppurative peritonitis. Bacteriological examination of fluid removed showed nearly pure cultures of the bacillus coli commune.

The second case was a child, eight years of age. Laparotomy third day. Appendix perforated and localized abscess of ʒ jss. of pus; appendix removed. Bacteriological examination of fluid showed diplococci pneumoniæ in nearly pure cultures. Recovery prompt. No cough present, nor could infection be traced.

In private practice it has been not easy to be always ready with a sterilized tube for the purpose of promptly receiving a fluid for a culture test; but lately, through the kindness of Dr. Ferguson, the pathologist of the New York Hospital, a number of small test-tubes with agar agar in them, and with a wire embedded in the cotton stopper, all duly sterilized, are kept ready in a small pocket book, such as is used to put tablet bottles in. These are easily carried in the pocket or operating bag, and will last several weeks, only spoiling by the drying of the culture medium.

Dr. J. D. Bryant also presented an appendix removed from a case three weeks ago. The patient had been under his observation at the hospital for hip-joint disease a number of years, and on one occasion he had removed three inches of the upper portion of the femur, including the head. The patient recovered from this operation but suddenly symptoms of appendicitis developed for which Dr. Bryant operated after forty eight hours. The symptoms were not severe; the pulse was 86, the temperature normal, the respirations about normal, abdominal distention very slight, so that he really felt some doubt whether there was involvement of the appendix. Yet at the operation he found that the appendix had sloughed through and general fecal infiltration had taken place, extending into the pelvic cavity and upward alongside the colon, there having been no effort whatever at limitation. Another experience in this case which was quite new to him was the fact that, owing to what might be spoken of as the rotten condition of the appendix, the first ligature cut through, and he had to apply a larger one, drawn less tightly, on the short stump. This patient, like all others seen by him in whom there was free escape of fecal matter into the pelvic cavity, died. The cause of the appendicitis was found to have been a fecal concretion.

Pathogenic Properties of the Bacillus Coli Commune.—Dr. Herman M. Biggs had last year studied a case of acute purulent pachymeningitis following typhoid fever, the attack of typhoid fever having been a severe one, convalescence having been protracted. About the seventh or eighth week the meningitis developed suddenly and caused death. He found in the lower portion of the small intestine a number of old ulcers that had not healed. Bacteriological examination of the exudate of the pia mater revealed pure cultures of the bacillus coli commune. He thought that observations made the last

two years had shown very clearly that under certain conditions the bacillus coli commune possessed very virulent pathogenic properties. Why at one time it was virulent and at other times not, had not been determined. He had seen two or three cases in which the clinical history was that of Asiatic cholera and the diagnosis had been made of that disease. The autopsy showed the anatomical lesions commonly found in Asiatic cholera, yet bacteriological examination of the intestinal discharges and contents revealed simply the bacillus coli commune.

The Treatment of Sterility, with Report of Cases.—Dr. William M. Polk read the paper.

Patency of the Ureter or Vas Deferens after Division.—Dr. R. F. Weir said he had been much interested in Dr. Polk's case of pregnancy after excision of the Fallopian tubes, as it gave the surgeon hope of patency being re established in the vas deferens or ureter should these by accident or otherwise be divided. In the case of the vas deferens there had been no positive proof of patency being re established through the cicatrix after accidental division in hernial operation, for the reason that the continuance of virility might be explained by function of the other testicle. In the case of the ureter, however, Kuster had had a case of division of this canal, and the re establishment of patency had been proven by observing through the cystoscope urine discharged from that side into the bladder.

Dr. Thompson supposed that in Dr. Polk's first case there must have been a Graafian follicle nearly ripe very close to the divided end of the tube in explanation of pregnancy. He also mentioned the fact that in the report of Lieutenant Peary's expedition to Greenland it was said to be the custom among certain of the Greenlanders for the men to exchange wives when there was no issue, and frequently the women became pregnant after the exchange, showing that there had simply been incompatibility.

Dr. Polk remarked that it had been the custom among Scottish clans for the chief to take another wife if there were no issue within a year.

Stated Meeting, May 5, 1893.

Charles L. Dana, M.D., President, in the Chair.

Aneurism of the Aorta in a Boy, aged Eighteen.—Dr. A. A. Smith presented a case of aortic aneurism which was almost unique in the early age at which it had developed. The lad, eighteen years of age, but having a more youthful appearance, had entered Bellevue Hospital complaining of beating of his heart. He gave a history of having had an attack of rheumatism a year ago, but Dr. Smith would judge from the size of his heart and the lesions apparent that he had had rheumatism before that date. The patient claimed to be pretty comfortable except for shortness of breath and a constant "cold." Although there was a cardiac lesion, that was not the point of chief interest to the pathologist, but rather an aneurism which involved the ascending and transverse portions of the arch of the aorta. Over this region there was a very marked thrill, decided dulness over quite a large surface, a double murmur, the thrill felt in the carotids. There was no history of trauma. Dr. Smith said he did not remember ever having seen an aneurism in one so young, especially of the aorta, nor had he seen the record of a case without trauma after the brief search which he had made of the literature.

Dr. Peabody, Dr. Biggs, and the other gentlemen present said they had not seen an aneurism of the aorta in a subject so young Dr. Peabody had seen two young men, aged nineteen, who had died of rupture of a miliary aneurism of the brain, but in both of them there was congenital narrowing of the aorta and larger vessels, together with arterial sclerosis, which usually accompanied that condition.

Dr. Abbe inquired whether it might possibly be a pulsating sarcoma in which a bruit was sometimes heard, but Dr. McBurney and Dr. Smith said the transmission of the bruit and thrill into the vessels of the neck was against that view.

Cases Showing Excellent Results of Skin grafting.—Dr. Charles McBurney presented two patients on whom he had employed Thiersch's method of skin-grafting for injuries of the hand and wrist, with most excellent results. The more recent case was that of a young man who had had his hand crushed on March 22d, while coupling cars, the laceration being so extensive that he was able to save only the thumb and forefinger. Even then there was no skin for covering, and one or more deep valleys existed due to absence of flesh. Skin-grafts were applied over the uncovered parts with perfect satisfaction. An interesting feature was the wonderful rapidity with which tissue had been reproduced beneath, filling up the hollows. There was no form of surgical dressing, as by rubber tissue or other means, which would produce such a result.

The second case showed the later results of skin-grafting. It was that of the boy whom he had presented several months ago, and who had sustained a very serious lacerating wound of the wrist by broken glass. The median and ulnar nerves, both arteries, and all the anterior tendons except that of the flexor carpi radialis were entirely divided, no injury having been done the posterior part of the wrist. The divided parts were sutured, the raw surfaces covered with skin-grafts, and there was a good result except for a dense cicatrix at one point which drew the hand to one side. The contraction had since been overcome, the influence of massage in this regard having been marked, and to-day the use of the hand and sensation were apparently normal.

Dr. Beverley Robinson could recall at least one case which had come under his observation, after the surgeon had done an operation for an injury and massage had seemed to do harm rather than good, increasing the nervous irritability at the site of the cicatrix.

Dr. McBurney thought that simple cicatricial tissue was very much benefited by massage, but where the cicatrix was keloid in character he thought it was detrimental.

Cerebro-Spinal Meningitis, with Hæmoglobinuria.—Dr. Herman M. Biggs presented a specimen of urine from a typical case of cerebro spinal meningitis. During the last twenty-four hours the urine had been passed in large quantities, was of reddish hue, as if mixed with blood, and on examination was found to contain some red blood-corpuscles, but not a large number, not enough to cause the deep red color of the fluid. It was a hæmoglobinuria rather than a hæmaturia. There was also considerable sugar in the urine. While glycosuria, hæmoglobinuria, and hæmaturia were known sometimes to occur in cerebro spinal meningitis, yet they were not frequent complications.

Being asked the history of the case, Dr. Biggs said that the morning of the day the man was taken ill he had worked, and at noon began to feel unwell, took a dose of Rochelle salt, rapidly grew worse, was transported to the hospital at midnight, when he had delirium and convulsive movements of the left side. The temperature was 104° F. He had been vomiting during the evening, and this continued more or less during the night. There was then rigidity in the back of the neck, contraction of the pupils, and delirium calling for restraint. The following day the head was drawn far back, convulsive movements still continued, more upon the left than upon the right side, the temperature somewhat more than 105° F. At night he began passing the discolored urine. Pulse, 140; respirations, 36 to 40. There was some twitching in the face and hands.

The President said he then had a case of cerebro-spinal meningitis under observation, and the patient was passing bloody stools. The case was running the typical course of cerebro-spinal meningitis, and typhoid fever had been safely, he thought, excluded. There was the sunken abdomen, stiff neck, delirium, hyperæsthesia, fever, etc.

A Case of Brachycardia.—Dr. W. Gilman Thompson sent the patient, with the following history, arriving later himself:

The patient who presents himself for examination is of interest on account of the remarkably slow, full pulse which he has had for some months, the average at present being between 28 and 20. He is a German, seventy-four years of age, of good physique. His general health has been excellent, and his history up to within a short period is unimportant. For the past four years he has had occasional attacks of syncope, but none of them were severe. About two months ago he had slight rheumatic pains in the left knee and shoulder, and some swelling of the feet. Thirty-eight days ago he entered the Presbyterian Hospital to seek relief from the latter symptom. During all this time the pulse has never risen above 36, even after exercise, eating, etc. I have counted it at 22, and it is usually just below 30. It is always full, strong, and regular. It does not become slower during sleep. The heart is slightly enlarged, the impulse beat being three-quarters of an inch outside of the nipple line. The sounds are distinct, but the chest-wall is very thick. No murmurs have been discovered at any time. The vessel-walls are only moderately thickened. Since the patient entered the hospital there has been no vertigo and no dyspnœa. His color is always good. The appetite and digestion are normal. There is never any disproportion between the number of radial and cardiac pulsations. There was at first a trace of albumin discovered in the urine, which later disappeared, and there is now again about five per cent. bulk of albumin, with granular, hyaline, and waxy casts. The œdema of the legs has nearly disappeared.

The man has regular habits, and has not abused alcohol or tobacco. His treatment has been merely tonic.

I have seen one other case which resembled the present one in infrequency of pulse-rate, but there was present decided mitral and aortic valvular lesion. In this instance the pulse frequently fell to 18, 22, and 24.

In an exhaustive article read by Dr. Prentiss, of Washington, before the Association of American Physicians,[1] he reported three cases of remarkably slow pulse, and reviewed the literature of the ninety one others which had been reported up to date. In one of these the pulse rate was 3 for several hours, and in another 4, afterward becoming somewhat more rapid. He reviews the etiological factors under the headings of diseases or injuries of the vagus or cardiac sympathetic nerves or their centres, of the intra-cardiac ganglia, disease of the heart muscle, and poisons.

Dr. A. A. Smith and Dr. McBurney remarked that the radial pulse was even more than usually full, and if they were to judge by that alone they would not suppose there was fatty degeneration of the heart.

Dr. Kinnicutt had never seen a case in which the pulse was so slow without there having been more or less cerebral disturbance. He remembered one case in which the pulse was 30, and when it fell lower than that the man would have an epileptiform attack.

The President said that he was once called in consultation, in the case of a man over sixty years of age, whose pulse then was from 6 to 10 per minute. This slowness of the pulse had occurred at intervals for some weeks. He would also have attacks of syncope which Dr. Dana thought to be due to anæmia of the brain. The patient finally died in one of the attacks. The diagnosis was fatty degeneration of the heart.

Malignant Endocarditis—Large Polypus.—Dr. Herman M. Biggs presented a heart with a large polypoid mass on the mitral valve. The patient, a man, was admitted to his ward about six weeks ago, apparently suffering from acute lobar pneumonia. The pneumonic process cleared up somewhat, the temperature went down, but rose again after two days, and continued rather high for three or four weeks.

[1] Transactions of the Association of American Physicians, vol iv, 1889, p. 120.

There were râles all over both lungs, a good deal of expectoration, and the diagnosis of probable general miliary tuberculosis was made. There was nothing to call attention to the heart. The patient failed and died with symptoms of pulmonary œdema. At the autopsy he found extensive miliary tuberculosis of both lungs and a small patch of old tubercular process at both apices. The spleen was very large, very soft, and contained two large infarctions, evidently from septic embolism. There were also several infarctions in the kidneys. The fact of interest was that on one of the mitral leaflets there was a polypoid mass which filled at least two-thirds of the mitral orifice. There was also a large fibrinous deposit on one aortic cusp. No petechial hemorrhages were noticed on the skin during life, but two groups of three or four small hemorrhages were observed on the side at autopsy. There having been no symptoms to call special attention to the heart during life, it was a great surprise to find so large a polypus of the mitral valve at autopsy. He had seen only one other case of so large a mass on the valve, it having occurred in a patient in the service of Dr. Janeway some years ago. Death took place in that instance suddenly, and Dr. Janeway made the diagnosis (on what ground he did not know) of polypoid growth on the right auricle, with detachment and plugging up of the mitral orifice, and all present were astonished when just that condition was found at autopsy.

Dr. Roosevelt said he had once presented at the Pathological Society, with other specimens, one of large polypus of the mitral valve of recent formation, an older and a larger piece having become detached during life and caused complete obstruction of the circulation in the lower extremities. The clot was large enough to obstruct both iliac vessels.

At the same meeting he had presented the heart of a man who had entered Roosevelt Hospital in 1881, was there a number of months, went out, and came back again after three or four years, with the same symptoms and died. When he entered he was a little less than twenty years of age, gave a history of rheumatism, and on examination was found to have a very loud, harsh, systolic murmur at the right of the sternum in the second and third interspaces. There was a thrill over the same neighborhood and lower. There was a systolic and a diastolic murmur at the apex, which was situated in the sixth interspace in the axillary line. There was no pain, no distinct signs of pressure on a bronchus. The autopsy showed great general cardiac dilatation, aortic insufficiency and no aortic stenosis, some mitral insufficient and slight mitral stenosis. The thrill and loud murmur had covered exactly the locality of the dilated right auricle which lay against the chest-wall. The case was sufficiently like that of the boy presented by Dr. Smith to be worthy of mention in that connection.

Acquired Immunity.—Dr. Roosevelt made some remarks upon this subject.

Dr. Biggs thought that in its ultimate analysis the theory advanced by Dr. Roosevelt amounted to the substitution of a vital for, according to the old idea, a chemical substance in the body in explanation of the immunity given by one attack of certain diseases. But it seemed to him there were certain facts opposed to this new theory as well. For instance, it was known that the susceptibility of individuals to all sorts of contagion varied at different times. Moreover, the susceptibility could be increased by the introduction of various chemical substances. It was a question of relation between individual susceptibility at the time and dose of the virus. If Dr. Roosevelt's theory were supposed to hold, that after one attack the old and susceptible cells were replaced by new ones which were not susceptible, following the law of survival of the fittest, he thought there would not be varying susceptibility at different times depending upon the presence of certain chemical substances. Again, he could hardly see how the theory could be reconciled to the fact that chemical substances might them

selves produce immunity, as in inoculations against tetanus and hydrophobia. There was no evidence that such substances when introduced into the system destroyed any of the cells.

Dr. Peabody said he could add nothing to the discussion, for while the subject was an interesting one, it was yet too transcendental to form a basis for practical conclusions.

Dr. Roosevelt, in concluding the discourse, said that the theory which he had advanced, like others, was not sufficiently tangible to admit of positive proof, but he thought it was unlike the others in that it could not be disproven. The arguments which he had advanced showed that the ground on which the chemical theory had been based was not tenable, and this was an advantage, as that theory had been taken as the starting-point for investigations which were intended to lead to practical results.

Trional as a Hypnotic.—Dr. F. P. Kinnicutt gave the results of experience with this new agent.

Dr. Peabody said that during a period of three months they had used trional in the New York Hospital in a large number of cases, and while they had found the effects which it produced about the same as Dr. Kinnicutt had described, still he and the house-staff had not thought it superior to the older hypnotic, sulphonal. The latter, when given in hot milk, produced its effects in fifteen minutes, and trional could do no better. The latter, however, was also efficient in gramme doses and was quite unobjectionable.

Dr. W. Gilman Thompson said trional had been used in twenty or thirty cases at the Presbyterian Hospital and the impression which he had obtained of its usefulness was like Dr. Kinnicutt's. It had acted very promptly in a case of alcoholic gastritis verging on delirium tremens. He had observed no depressing effects from it, but when thirty grains had been given as a commencing dose the drowsiness had sometimes lasted until noon or in the afternoon of the next day. It had acted in most cases, if it acted at all, very promptly, certainly within half an hour, often within fifteen minutes. He had never observed the vertigo and depression which sometimes followed the use of sulphonal. It could be taken easily dry on the tongue.

Correspondence.

DOCTORS IN POLITICS.

To the Editor of the Medical Record.

Sir: Medical journals constantly lament the indifference of members of the profession to political matters, and lack of representation in municipal and legislative bodies. As a necessary result, the doctor and the doctor's interests, and the community in which he is an important factor, all suffer.

I do not think this indifference prevails in Maryland, and know it does not in old Anne Arundel County. Many years ago I saw the most powerful political organization broken and defeated by a combination of two doctors, in a district where there was apparently, in the opinion of all the knowing ones, no chance for a fight. After the victory, an old negro man expressed the universal sentiment of the people, including the politicians, "dem doctors am de debbil." It is needless to state that at the next election the politicians did not fight the doctors, but were genial, kind, clever, took them by the hand, conferred with them in making the ticket, and finally sent one of them to the legislature, where he could vote upon bills relating to his professional interests and see the vote counted.

As early in the history of the country as 1655, religious and political strife culminated in a bloody war at the mouth of the Severn River, and among the many remarkable characters participating in the stirring events was a member of the medical profession, Dr. Luke Barber. From that period to the present, nearly two and a half centuries, every generation, every war, assembly, or convention where the "rights" of the people were in jeopardy, I think the records of Maryland—not assertion or tradition—will show that the "doctor" was there, and that he did his duty.

J. M. Worthington, M.D.

Annapolis, Md.

CHARCOT.

To the Editor of the Medical Record.

Sir: There are two persons here who were waiting till Professor Charcot got back from his vacation in order to consult him; one was from California, the other from Dresden. This I mention to show the world-wide extent of the lamented physician's reputation. Perhaps no medical man in modern times had become so extensively known among the laity, and so highly honored by the members of his profession. Whatever there is or was to be gained in the way of reputation, position, fortune, and scientific achievement he had done. French medical science was particularly indebted to him, for he not only created for it a new and most important branch of practical knowledge, but kept it fully abreast of German, English, and American work. While France fell in recent years so lamentably in the rear as regards surgery and many departments of medicine, the neurological school has been constantly turning out industrious, fruitful, and original workers.

Knowing this I have been reading with much interest the comments of the Parisian press on the life of the man who did so much for the glory of France. The result has been to create some doubt as to whether Charcot was really much of a man after all. Most of the papers give a half-column perfunctory notice, containing a sketch of his life, and a very incomplete account of his work. *Figaro* alone takes the trouble to employ a competent writer, and devotes to him nearly a column, which is quite as critical as it is laudatory. Charcot, according to M. Gautier, was a great scientist whose word was law on two continents; but, perhaps, he adds, he was more esteemed out of France than in it. A writer in *Gaulois* seems to think that a Dr. Blanche, who died on the same day, and of whom I confess I had never heard, was quite as great a man in his way.

Charcot, says *Figaro*, was accused, not perhaps without some truth, with an absorbing egotism and an intense passion for *réclame*. He aimed to be continually posed before the public. This is a side of his character which, if true, was not noticeable to us who judged him by his writings alone. His French eulogists, if they may be called so, seem to think that Charcot's greatest work was in the direction of hypnotism, and that when the world has forgotten all else that he did it will still remember that he first cleared up the mysteries of animal magnetism, mesmerism, and similar *diableries!* This is the astonishing conclusion reached by a writer in the leading journal of Paris. As a matter of fact, Charcot contributed little that was new or valuable in this department of research. On the other hand, his name is inseparably connected with researches upon the pathology of apoplexy, asthma, tabes dorsalis, paralysis agitans, various scleroses, hysteria, aphasia, and many other forms of disease. Perhaps his greatest work, after all, consisted in utilizing constantly and intelligently the enormous opportunities offered at the great poor-house of Salpêtrière.

Charcot married a rich widow, and her fortune enabled him from the first to pursue his scientific work without the cares incidental to working for a practice and a living. He cared much less for his private practice than for his scientific work, and he was said to care more for interesting cases than lucrative patients. He was fond of music, painting, and the arts. Charcot was, according to his biographers, a "taciturn." He was not approachable or companionable in his ordinary professional relations. He preserved with his pupils the attitude of a master. This system of pupil and master, which Charcot

illustrated so well, had its good features and produced excellent results, for by it a wise control was exercised over the work of the younger neurologists. Their labors were concentrated upon certain fields, and rich opportunities for study were furnished to younger men.

On the other hand, the masterful temper of Charcot prevented anyone in Paris from becoming but a secondary light. Now that the master is dead, there are no successors. Paris has a number of able "pupils" in neurology, but no one who has secured anything like the reputation which Charcot held.

There is already talk of Professor M. Raymond filling his place. Raymond has written one good book and one very bad one. He is hardly looked upon as a neurologist by the profession in general. Charcot was a man of large physique and striking presence. He had the stooping shoulders and something of the physiognomy of Napoleon.

He had an attack of vertigo during one of his Monday lectures and started soon after on a vacation in company with Debove and Dejerine. On the night before his death he sat up chatting with his companions and making plans for the morrow. He then went to his room. Next morning he was found dead in his bed. On the table was an unfinished letter to his son. His last lines were, "I will finish to-morrow; I will now go to rest," and so he went to his last rest. C. L. DANA, M.D.

LUCERNE, August 18, 1893.

ABDOMINAL HYSTERECTOMY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: My attention has just been directed to the letter of Dr. J. S. Pyle, of Canton, O., in which he claims priority in the use of clamps in abdominal hysterectomy. As I have already informed Dr. Pyle, my first operation by my method was made in a public clinic in this city in July or August, 1890. If the doctor can say that he had even thought of the procedure at the time my operation was made, I am perfectly willing to ascribe to him the credit of originating what I have termed "Lanphear's method;" if he cannot, then I must claim whatever honor there is in a method that can, at least, be recommended only in cases where total extirpation by the use of ligatures cannot be followed, for the reasons set forth in my paper published in the RECORD of July 1, 1893; a method which, I must confess, has attracted more attention than its merits deserve. Very truly yours,

EMORY LANPHEAR, M.D.

KANSAS CITY, Mo., August 19, 1893.

PURULENT OPHTHALMIA—IMPERFORATE HYMEN—A QUESTION OF MICROBES.

TO THE EDITOR OF THE MEDICAL RECORD

SIR: Dr. Alfred Hinde, in the RECORD of July 15th, this year, in an article entitled "Purulent Ophthalmia, from the Stand-point of its Specific Microbic Cause," makes assertions that I do not think can be substantiated. As almost the whole article is dependent on the first paragraph, I will only notice that. He says: "That all cases of purulent conjunctivitis are of microbic origin and due to Neisser's gonococcus." My principal reason for disputing the above paragraph is that I have treated purulent conjunctivitis that did not so originate. You may say that is only the assertion of one observer. I know it well enough to be able to go on the witness stand and swear to my conclusions. I had binocular purulent conjunctivitis last summer myself. It originated from an irritant, driving through hot alkali dust on the prairie. I saw a case only a few weeks since that was not of gonorrhœal origin. The case happened in the family of my nearest neighbor, the subject a child, nine months of age, and as I am personally acquainted with all the family surroundings, and from the peculiar isolating circumstances surrounding the child before the disease, am equally as positive as in my own case. In this case the disease was monocular. I will readily admit that purulent conjunctivitis is oftenest caused by gonorrhœal infection, but will never admit that all cases are so caused. I do not admit, though, that the gonococcus is ever the cause of conjunctivitis, nor of urethritis. Some of our most eminent physicians claim to find true gonorrhœa without the gonococcus. I would like to have that phenomenon explained, if phenomenon it is, else I cannot accept the microbe theory of gonorrhœa.

It seems that we are going wild over microbes. Though only an humble country practitioner, and fully realizing the seeming egotism in the prediction, yet I do predict that in ten years from to day we will laugh at our folly in ascribing diseases to microbes.

Do not understand me to say I do not believe in microbes. We must believe in what we see. I believe the bacillus tuberculosis is as much of a scavenger as the vulture

Too many of us talk in a positive way about "inflammation," "bacterial infection," etc., when we do not know what we are talking about; yet some of these very men are teachers.

On one of the hottest summer-days of 1891, the writer was called to dress a scalp wound inflicted upon one railroad section hand by another. The wound was both contused and lacerated, and was made by a powerful blow with the back of a shovel. The man had on an old slouch hat at the time, and though the blow did not cut the hat, the scalp was split in three directions from a common centre to the extent of one and a half inch each way from said centre, thus laying the skull bare over an area of at least two square inches. Now, with an old, greasy, slouch hat mashed into the wound, and with a scalp crusty with several weeks' accumulation of dirt and the oily excretions of the skin, we surely had the ideal wound for "bacterial infection." You will of course say we had a suppurating wound very slow of healing. We did not have anything of the kind. I put some boric acid in warm water, using an old dirty tin pan as container—could get no better—and washed off the blood and as much dirt as possible, and shaved the wound margins and closed with silk sutures. Powdered with boric acid, put on gauze, cotton, and plaster. The result was "union by first intention," no pus. Do not understand that I disbelieve in asepsis. I carry it out fully when circumstances permit. Asepsis is simply cleanliness; and "cleanliness is next to godliness," so we are told. We should be clean if only from force of habit. The point I wish to make is, that it is silly to go into spasms over contamination from contact with some unsterilized student or clinical assistant, as we often see some of our learned professors do.

Dr. Charles E. Nammack, in his article on "Imperforate Hymen," page 81 of RECORD—same date as above referred to—says: "The patient made a speedy and satisfactory recovery. The case seems to show that the danger formerly attributed to rapid evacuation of these accumulations can be obviated by asepsis." Now, doctor, don't you think you ought to state it this way: That if death had resulted it would have been from "shock" caused by the sudden withdrawal of so large an amount of fluid; or from hemorrhage from tubal rupture; or from traumatic peritonitis—peritonitis from tubal rupture, or some similar traumatism? It is to be supposed your patient would have died without operation, so don't you think it was the operation and not the asepsis that did the work?

I once performed a laparotomy in which my assistant wiped the saliva from the patient's mouth with his fingers and immediately thrust them in the abdominal cavity. The wound healed with a temperature not higher than 101° F., and with no pus except a few drops at a stitch-hole. Such an assistant as the above is not a very desirable one, but we have a few such.

Truly the microbe is passing through a period of persecution; but we will some day "arise and call it blessed."

THE MANAGEMENT OF ECZEMA IN CHILDREN.[1]

By ALBERT E. CARRIER, M.D.,

DETROIT, MICH.

Fully one-half of the cutaneous affections that occur in children under the age of five years are cases of eczema, and as they are all treated by the family physician, it is to the general practitioner that the specialist must look for the best therapy of the disease.

I think that it is our fault that many of these cases of infantile eczema occur. I think that it is our fault that they are allowed to continue for an indefinite period without treatment. I think it is our fault that when they come under our care they are not sooner cured.

Eczema in the adult, or in the child, is a perfectly curable disease. Eczema should be cured as rapidly as possible, no matter how small or how large a surface may be affected. The skin of the adult is a very complex and delicate structure, that has passed through its period of growth, and with its hardened epidermis it is in a comparative state of rest, able to resist and to repair injuries. The skin of a child is much more delicate, and more than this, it is growing, and its epidermis is very much softer than that of the adult, and yet it receives the harshest treatment at the very beginning of independent life.

During the life in utero the child lies in a bland alkaline fluid, of constant temperature, and is covered with an oleaginous substance that prevents any liability to maceration of the epidermis, and also protects it from the irritation of discharges that it comes in contact with in its passage to the outer world. At birth the babe it ushered at once into a gaseous envelope, with a drop in temperature of 20° to 40° F. Usually our first attention to the child is when the nurse asks about the dressing of the cord, and we find the babe wrapped in a woollen blanket, and its skin from head to heels as red as a boiled lobster, while kicking legs, flying arms, and lusty cry, attest its protest against the treatment it has received. The nurse has done her duty in a most conscientious manner. In the first place she greased the baby, using either lard, butter, bear fat, goose oil, skunk's oil, olive oil, or vaseline, according to her individual preference; rancid or not, it has been thoroughly applied and rubbed over the surface.

The next process is the getting rid of the fat by the use of soap, and here again the selection has been left to the nurse, or to the mother, and we find a nasty perfumed preparation has been used whose irritating properties are in direct proportion to the perfuming; this has also been thoroughly rubbed over the skin. To remove this, hot, cold, soft, or hard water is used, and the climax of the whole process is reached in the drying, and the attempt to establish the cutaneous circulation by briskly rubbing the skin with the hands, or often a harsh cloth. The probable result of this is the loss of the outer layer of epidermal cells, the natural protector of the skin.

After this comes the clothing, which is woollen next the skin, and tightly drawn together. It is a common thing to see a nurse attempt to put a fifteen-inch belly into a twelve-inch band. If the child survives these first assaults upon its skin without the development of a salt-rheum, the irritation of the daily routine of babyhood, with the daily baths and the extra bathing to meet emergencies, the exposure to temperature changes, or the direct rays of the sun, etc., may cause an inflammation to occur that speedily becomes eczematous.

Between babyhood and the age of five years the child is independent, and helps by its own actions to add irritations to an already sensitive skin, by scratching it with dirty nails, handling bugs, toads, spiders, etc., having a holy horror of all principles of hygiene, asepsis, or antisepsis, the outcome of which is likely to be an eczema.

So far I have called attention to irritations that might be called normal, as they consist of the surroundings of nearly every child from babyhood until the age of five years is reached, but other local causes will readily occur to the reader, such as pediculi, the itch mite, eruptive fevers, etc., either of which may be the cause of an eczema.

Eczema results from an internal or an external cause. From what I have said it might be inferred that I hold external agencies responsible for all eczemas in children. Do not so understand me, but I do believe that the largest number of cases are due to external causes, and as evidence of this stands the fact that eighty per cent. of the cases attack the face and the scalp, parts most liable to injuries.

Internal causes for an eczema are as various as are the internal organs. We can easily comprehend the relation of external agencies in the causation of an eczema, the local irritation setting up an inflammation that speedily becomes eczematous; but it is more difficult to explain the relation of a slight affection of some internal organ to an eczema that may only occupy a very small portion of the skin. Clinical experience proves, however, that such relations do exist. Most of the cases of internal origin will be due to some disturbance of the digestive tract, and are in the majority of instances due to improper feeding.

Foods for babies are as numerous as the grains of sand upon the seashore. There is but one food for a baby. Improper feeding may consist of too much or not enough of proper food. A fat baby is no more healthy on that account than is a lean one sick because it lacks fat. Fat, even within moderate limits, may be a pathological condition in a salt-rheum. Organic or functional disease of lung, liver, heart, kidney, or spleen, of even trifling nature, may develop a salt-rheum, or when once established keep it in existence.

I know of no skin disease that, being curable, so taxes the patience of the sufferer, or the skill and ingenuity and patience of the physician, as an eczema in the adult, unless it be the same disease in the child.

Salt-rheum of the child is salt-rheum of the adult, plus the extra liability of the child's skin to injuries, and the tendency to reflexion of gastro-intestinal affections to the cutaneous structures.

To preventive measures I attach the greatest importance in the management of this disease. I think that every new-born child should be treated as liable to an attack of eczema. Having this in view, directions for the care of the new-born would be pretty explicit, we would see that proper materials were at hand for the cleansing process, and that they were properly used with the profoundest respect for the skin; the fat or oil that is used to remove the sebaceous matter must be of the blandest kind, and one that is not liable to decomposition nor to the ravages of a microbe; lanolin, and the petroleum

[1] Read before the Michigan State Medical Society.

products furnish such. The soap must be perfectly neutral, an excess of alkali in a soap makes it very irritating. Pears' unscented transparent soap comes the nearest to a neutral soap of any that I have tried. The water used in washing must be soft and warm, not hot, and the wash cloths of fine old linen. The drying of the skin should be by simply mopping it, and this should be followed by a little fat smeared over the body. Woollen clothing must not be worn next to the skin, and all clothing must be held in place loosely. The same minute attention to detail throughout babyhood will probably avoid an outbreak of the disease, as far as external agencies are concerned.

Nursing children are very easily affected by the mother's milk, and a diligent inquiry of the mother in a given case may reveal the fact that she has a slight dyspepsia, or a tendency to gout, or rheumatism; or we may find that her habits of living are bad, she may take her food at irregular intervals, or she may be in the habit of using beer, ale, or porter, with the intent of increasing the supply of milk. Malt liquors are not good for the eczematous, and they are no better when strained through the mother. The child may be fed irregularly, or given too much or not enough at a time. Many of the eczemas occurring in children who seem to be otherwise in perfect health, may trace the cause of their disease to one or other of these faulty conditions of the mother.

After the child is weaned, its diet must be carefully attended to, the food must be nutritious, and easy of digestion. All rich foods must be avoided—pastries, gravies, puddings, sauces, and all fried foods are not good for the eczematous, nor are candies and too much sweets. Sometimes fat food is not taken in sufficient quantity. Diet regulating in these cases of infantile eczema is of the utmost importance, and we may be agreeably surprised when some rebellious case is speedily cured, when a trivial diet error is corrected.

Eczema always tends to become chronic, and no matter how small a surface may be attacked, it should receive our attention at once; cases should not be left to nature, nor treated expectantly; here is where we often make an error, and are responsible for the disease continuing an indefinite time. Attack the disease at its very beginning, and you may speedily cure it, but let it get well under way, and you may have a severe siege before it is overcome.

Eczema is an inflammation of the skin, acute, subacute, or chronic, and catarrhal in character. In the medicinal treatment of the disease we are to avoid both over and under medication. A routine practice will never satisfactorily combat an eczema. Treatment must be active and persistent, varying with the various conditions of different individuals, or in the same individual at different times in the course of the attack.

Internal medication will be directed to the removal of diseased conditions of other organs than the skin, and to discuss this would require an essay on general therapeutics. He who is the most successful in the practice of general medicine, will not so often call to his aid the so-called specifics for skin ailments, such as arsenic, mercury, etc.—remedies powerful for good in selected cases, but better left out entirely than to be used indiscriminately. In the cases where we are unable to find any internal cause for the eczema, we may give remedies for their direct action on the skin. The acetate of potash, or other saline diuretics, are of great value in reducing the blood pressure in affected areas, or the saline cathartics may be used for the same purpose. There is one remedy that I think of great value in acute cases, in the full-blooded, red babies, viz., antimony; it must be given in small doses and not too long continued.

A district in which the malarial toxæmia taints every disease (and this is the case in nearly every portion of our State) will be apt to exert a pernicious influence upon an eczema, and many of our little patients will need antimalarial medication before the skin affection yields. Quinine and iron will be needed, but it is difficult to get children to take quinine. I usually give it to the mother if the patient is nursing, and if weaned use it in ointment or suppository.

Local treatment is of greater importance as far as the special medication of the eczema is concerned. Many cases will continue even after the cause is removed, the skin becoming habituated to the disease. Soothing measures are required in acute cases, while stimulating remedies will be called for in subacute or chronic cases. Tar as an application in an acute case will do positive harm, while oxide of zinc, in an infiltrated patch of chronic eczema will as positively do no good.

Don't use plain water in an eczema that is acute, the washing of such a surface will completely undo your work. Don't fail to protect an acute eczema from the air, and if it is on the face keep the patient indoors when the wind blows. All scales, crusts, etc., must be removed before applications are made, so that the remedy may be brought into direct contact with the diseased surface, and this is better done by soaking the part with some fat until the scales are soft, and then gently removing with a mucilage of marshmallow, or flaxseed. The remedy must be ready for immediate use. To afford protection, to constringe the vessels, or to soothe the parts, remedies must be applied continuously, and may be in the form of powders, pastes, liniments, lotions, or ointments; but which to use in a given case is a matter of importance, and how it is to be used is of more importance. To direct that an ointment must be rubbed in night and morning on a patch of acute eczema, will do more harm than good. It must be spread thickly upon a cloth, and kept in place by bandages, removing when scales or crusts have formed; but this may not be necessary for several days, the longer the better, as it protects the young epidermis. Ointments are useful when the discharge is moderate, and when hairy parts of the body are involved. With a profuse discharge, lotions or powders are to be used. A liniment is preferable if the remedy is to be applied continuously to a large surface, with free discharge, and is used by saturating cloths, and applying closely to the part. Powders should never be used when the hairy parts of the body are the seat of this variety of eczema, as with the exudate they form crusts, matting the hair, and confining the irritating discharge; nor should they be used between diseased surfaces, as by their caking they form irritants with every motion. Mild, non-irritating antiseptics may be added to soothing applications with benefit. In all pustular eczemas, bactericides are called for, and of these iodoform stands at the head. It is this variety of the disease that has been called contagious, but it is only so in the same sense that are all pustular inflammations due to a pus coccus, transference of which to an abraded surface may develo[illegible] pustule. The dry, itching patches on the cheeks [illegible] forehead, or small patches of the disease with only sli[illegible] discharge, are best treated by the gelatine pastes, wh[illegible] may be painted over the parts once or twice a day. [illegible] soon as the disease has passed the acute stage, the tre[illegible] ment changes to one of a mildly stimulating charact[illegible] but always using the mildest remedy that will do [illegible] work. In these cases the applications are to be use[illegible] intermittingly. With marked infiltration severer measures must be used, and it is in these cases that the mercurials are of so much benefit. Soothing remedies should always follow an irritating application. A very distressing symptom of all varieties of the disease is the pruritus, and the efforts of the child to relieve this by scratching, will often undo in a minute the benefit that we have worked days to accomplish. The child must be prevented from scratching by force, until we can control the pruritus. This is often the most difficult part of our therapy of eczema. Antipruritics, such as thymol, menthol, tar, and carbolic acid are all useful; one of the best remedies for this purpose is "liq. carbonis detergens" diluted with water and mopped over the surface several times a day, following the application with a powder, or a little fat. I have confined my remarks to the discussion of principles, and indications, rather than to special

medicines, and the few mentioned are all familiar drugs. I have purposely left unnoticed the latest remedies recommended for this disease, because I think better results will be obtained from the use of the drugs with which we are familiar, than from the use of the newer ones that may have only a single case to recommend them.

14 Adams Avenue, West.

EMPTYING THE UTERINE CAVITY BY ARTIFICIAL DILATATION. A NEW BAG FOR ITS ACCOMPLISHMENT.

By J. S. PYLE, M.D.,

CANTON, OHIO.

Not infrequently the gynecologist is confronted with the subject of inducing premature labor, or emptying the uterine cavity for various causes; the obstetrician meets with many cases where artificial dilatation of the cervix would be preferable to hours of suffering, and the first thing to engage our attention under such circumstances is the means at our command. We next study the requirements and nature's method of performing the work, and ask ourselves if any known device will secure dilatation as effectually and with as little danger to both mother and child? Such a contrivance would certainly be desirable, and we are safe in saying that nothing, in general use up to the present day, has ever approached such perfection. It would be presumptuous for any person to assert that this would be impossible, as nature's methods are being paralleled every day by the inventive genius of man. In this instance we are greatly assisted by seeing the operation performed almost daily, and it would be strange indeed if some one did not undertake to imitate the process. An attempt was made some years ago by Dr. Barnes, of London, England. His contrivance, however, was far from fulfilling the requirements; and inefficient as it proved to be, it came into general use for the want of something better. Dr. Barnes made a mistake in the choice of the material out of which his dilating apparatus was to be constructed; and had he looked to the "bag-of-waters" for the solution of the problem this error would not have occurred. Elasticity is not a property of the membrane that enters into the formation of the bag-of-waters. If this property existed to a marked degree it would be impossible to effect dilatation, as the membrane would simply be obtruded, the dimensions of the amniotic cavity increased, and the whole force of contractile energy of the uterus would be expended upon an expanded surface, thereby diminishing the dilating force and interfering with the progress of labor. An elastic apparatus, such as Dr. Barnes's bag, is far more harmful in its use as a uterine dilator in the commencement and during labor than it would be if the same property was imparted to the membrane constituting the bag-of-waters. In the latter case no alteration to the normal presentation would be witnessed, while in the former this would be a serious objection. Instead of securing the dilatation, the elastic material out of which the bag is made, when put under the required pressure, bulges out balloon-fashion, displacing the uterine contents, and exerting a great tendency in favor of abnormal presentations with a dilating force equal only to the resistance of the elastic rubber. This is far from what is at all desirable, and is, I might add, dangerous. So much for elastic material and Dr. Barnes's bag; and if our allegation be genuine, what can be said in favor of an inelastic, impervious dilating bag, made sufficiently large to secure full dilatation for the passage of the oncoming head. Such an apparatus is represented in Fig. 1, upon which our remarks will now rest.

More than a year ago my mind was occupied with the subject of constructing an inelastic bag to be used by the gynecologist and obstetrician as well. My labors were somewhat impeded by the delay in selecting a material that combined the proper strength and delicacy of texture. This was a question upon which much depended, as I was aware that it would have to be made of material that would occupy the least possible space when inserted. My mind at last rested upon bolting silk; and forthwith a sample was obtained and forwarded to the Hodgman Rubber Co., of New York, for being treated with rubber to render it impervious to water. This was promptly returned prepared for working up into the article required. The form of the bag was the next thing in question, and here I spent considerable time experimenting. A cylindrical shape was decided upon, and at first it seemed a great advantage to shorten the vertical axis by the use of silk cords; but this soon proved to be unnecessary, and the trial bag was made without this addition, and with just enough material in the top and bottom to form a right angle with the vertical axis. Of course it would be impossible to retain this flattened surface where there is the slightest elasticity, as there is in all woven fabrics; but the loss in this adds little to the convexity and does not impair the usefulness of the apparatus. The transverse diameter decided upon

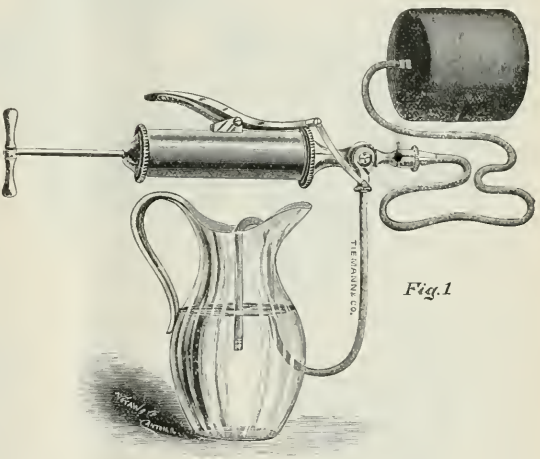

Fig. 1

was three and a half inches; the vertical, three inches. The seams were united with rubber cement, and to assist in this it was found necessary to have a form that could be taken apart and removed in pieces before the opening in the side of the bag was closed. The latter can be cemented without any support. After all this, which represented a great deal of labor and patience, a trial bag was secured and put to the test; but as its power of resistance fell short of my expectations, I proceeded to find a stronger fabric, and one that would answer the same requirements. The raw silk prepared by the Chinese was chosen this time, and treated as before. The bag made from this material was put to the test and answered every requirement quite up to my anticipations. I have had it in use for the past eight months, and will be able to give an account of its operation and the cases in which it proves of the most service. The appearance of the bag when it is in position and operation is well shown in Fig. 2.

Its introduction is effected by inverting the distal end, folding the sides in until it occupies the least possible space, and carrying the compact mass through the cervix up to the child's head. Here it should be pressed firmly, while the reversible acting pump, shown in the illustration, forces water enough into the bag to expand it. The effect produced is to carry the top end out beneath the membrane and between it and the cervix, and in the same manner expand the lower end to which the tube is

attached—giving it the shape of an hour-glass. When the bag is full of water it is self-retaining, and to secure dilatation all that is necessary is to place the liquid under pressure. This is the dilating force; and with the double-acting pump uterine contractions may be imitated and the dilatation secured in a most natural way. As the bag is being filled and the dilatation progresses, it acquires a cylindrical shape; and when the capacity is completely satisfied, it will be forced out of the cervix by the on-coming head, and may be used to dilate the vagina in like manner. In cases of labor where I have

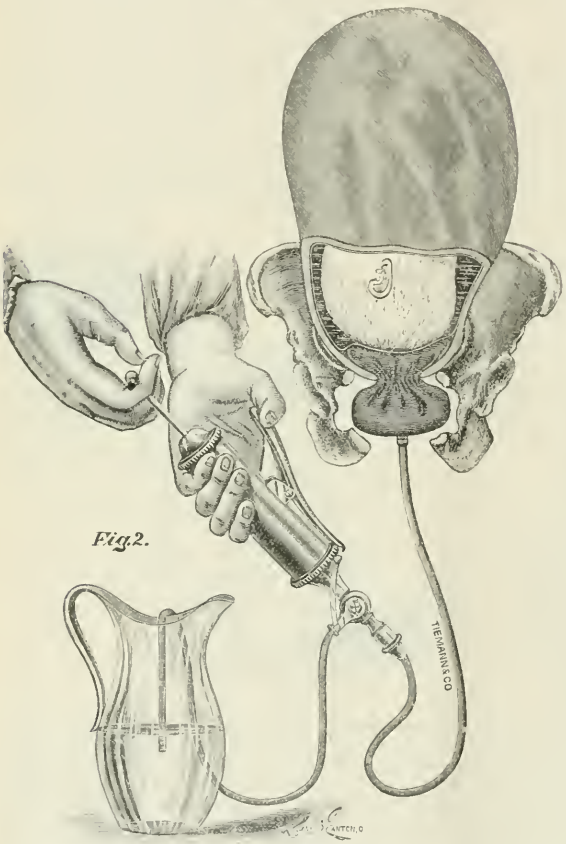

Fig. 2.

used it, I proceeded by dilating the vaginal passage first, so as to allow the greatest freedom to the introduction of the hand in inserting the bag. The operation appears simple enough, and is not difficult; but great self-possession and collectedness are required if we hope to become adepts and work with any satisfaction. After the bag is in place, gentleness and a well regulated pressure with intermissions should be observed. It allows the cervical tissue time to become œdematous and softened, thereby favoring the perfect dilatation of the parts. Care should be exercised not to let too much of the bag enter the uterine cavity, as it would displace the contents and probably encourage abnormal presentations; but this is not likely to happen if it is introduced while the uterine contractions are in progress, as the head will be forced down and prevent the bag from ascending. To the obstetrician the instrument is very desirable in painful labors, cases of uterine inertia, or where the tissues of the parturient canal are highly resistant. By it the hours of labor may be shortened and the patient relieved of a great deal of suffering and muscular exertion. In fact this is so marked that one is tempted to use it in the majority of cases, and I believe to a great advantage. For the induction of premature labor no instrument now in use will take its place. The rapidity of dilatation is under the direction of the operator and may be accelerated or allowed to progress slowly at pleasure. Water is used exclusively as the dilating medium, and the parturient canal, as well as the apparatus, is thoroughly disinfected. The use of the bag is extended to all cases where the uterine cavity is to be emptied or explored. Its value is inherent in its inelastic property and delicacy of texture. The former contributes to its resistance and the maintenance of the cylindrical shape, and the latter to its ease of introduction and wider range of application. The instrument is made by Tiemann & Co., of New York

68 West Tuscarawas Street, July 12, 1893.

IMPETIGO HERPETIFORMIS.

By M. B. HERMAN, M.D.,

Memphis, Tenn.,

Visiting Surgeon to St. Joseph's Hospital.

E. McC——, aged twenty-three, married, American, of healthy parentage, her father and mother both living and enjoying good health; one brother has had dropsy, two years ago, but is in good health now. She began to menstruate at seventeen years of age and has been irregular ever since, going sometimes for four months without a return of the flow.

In 1889 she had typhoid fever, lasting eight weeks. After her recovery her health had been good up to August, 1892, when she was attacked with severe pains and swelling in both ankle-joints, which was quickly followed by painful swelling of both knees and shoulders. Three months later, and while still suffering somewhat from arthritis, she was taken with a chill, fever, pains in her limbs, and nausea, and the following day noticed a vesicular eruption around her mouth and neck, which soon became pustular, and gradually involved the whole face, scalp, upper and lower extremities. She had no treatment up to February 28, 1893, when, after a trip of seventy miles in an ox-wagon, she was admitted into St. Joseph's Hospital, where she came under my care the following day. Her hair was cut short and was matted together. The whole scalp was a mass of pustular patches covered with soft yellowish crusts, which, when raised, discharged a large quantity of very offensive pus. The face, back, and extensor surfaces of the arms, flexor surface of the legs, as well as the posterior and inner aspect of the thighs, were covered with brownish-black, irregular crusts.

The neck, hands, and abdomen were free from any eruptions. Some discrete vesicles and pustules the size of a hemp-seed to a split pea, and a few groups of pustules the size of a ten-cent piece were scattered over the sternum and feet. No areolæ surrounding the crusts were visible except over each knee. There was no pruritus, nor had there been any since the beginning of the disease, and then it was only slight. Patient was free from glandular enlargement. The removal of the crusts with a paper-cutter exposed red superficial ulcers slightly purulent. Patient complained of sore mouth and swelling of the gums and fauces. She said she thought that was due to ptyalism caused from a dose of calomel which she had taken a few weeks before coming to the hospital. There was no abnormal flow of saliva at the time. The inability on the part of the patient to open the mouth prevented me from making an examination of the fauces,

but I am inclined to think that the lesions involved the mucous membrane of the mouth also. She still complains of pains in her limbs and joints, but no swelling; both knees are anchylosed.

Her temperature when admitted into the hospital was 101° F.; pulse, 126; bowels regular; tongue, as near as I could see, was clean; appetite fairly good, but could only take liquid food on account of her inability to masticate.

Two weeks after her admission into the ward she had a very severe attack of facial erysipelas; her temperature rose to 105½° F. for nearly four days; the face became very much swollen. The attack lasted six days. At first the improvement was slow, but after she was able to take nourishment freely the improvement became more pronounced.

As soon as the patient came under my care the crusts on her face and body were removed by the use of sweet-oil freely applied with a paint-brush, the scalp was cleansed with soap and water and a five per cent. solution of carbolic acid poultices applied; these were covered with gutta-percha tissue and bandage and renewed daily. In a few days the scalp was entirely free from crusts and the pustular patches were covered by a luxuriant growth of granulations. An ointment of white precipitate, grains x. to ℥., was applied, but soon replaced by another of three

per cent. carbolic acid, which was used continuously on the scalp and alternately on each side of the body. Internally the salicylates were given until all pain in the joints had disappeared, when tonics, arsenic, strychnine, iron, quinine, and malt were substituted with a full nourishing diet. Her appetite improved very much; she was constantly asking for food. She gained very much in flesh and strength. The large superficial ulcers, which looked red and shallow after the crusts had been removed, formed into decidedly "elevated" irregular cicatrices, with occasional new crops of pustules at the periphery. These fresh irruptions were usually accompanied by a rise in temperature of from 1° F. to 1½° F. and slight anorexia, which, however, subsided in a couple of days. No new lesions had appeared for three weeks prior to her leaving the hospital. She was discharged, apparently cured, on May 21, 1893, and left for her home in Mount Pleasant, Miss., feeling perfectly well, and with the promise that she would keep me informed if a relapse should occur.

The case has been of great interest to me, as it is the first case of impetigo herpetiformis which has ever come under my care. This is the second case reported in America.

According to Hardaway [1] some thirteen cases have been reported, twelve of which proved fatal, and the patient that recovered suffered many relapses, and the two who recovered from former attacks died later from the same disorder. Eleven of the cases reported occurred in pregnant women. Of the thirteen cases on record, twelve were reported by Hebra and Kaposi and one by Heitzmann.

SUPERFICIAL LACERATION OF THE FEMALE PERINEUM.

By FREDERICK P. HAMMOND, M.D.,

NEW YORK

In the evolution of research concerning the female perineum and its diseases, a few suggestions do not seem out of place concerning the pathological changes which take place following a laceration of the skin and superficial connective tissue. Our older teachers and many of the present day deal with the area of tissue between the vagina and rectum as the perineal body, and teach that its main function is the support of the female pelvic viscera. The newer school, unable to believe Nature had been so imperfect in her work as to leave the important organs of generation dependent upon a mass of connective tissue and skin for their support, sought for and found the more logical pelvic floor, consisting chiefly of the levator ani and triangular ligament. But these, having found the true support of the pelvic viscera, have in their enthusiasm lost sight of this still important organ, the perineal body. For in a degree it still remains a body, and its function is hardly less important than our older teachers held, for it closes and protects the vaginal outlet from the atmosphere and friction of the clothing, and affords support for the superficial perineal muscles.

From a careful observation among dispensary patients and in my private practice, I have taken special note of the existing condition of affairs in all cases presenting themselves where a laceration of the superficial perineum or relaxation of the pelvic floor due to a division of the fibres of the levator ani has existed, and in both the resulting pathological condition has been the same. From my observation, therefore, it seems conclusive that the more modern teaching of a slight laceration of the superficial perineum being harmless, further than for its cosmetic effect, is entirely erroneous. For if any gynecologist wishes to convince himself that hypertrophy and œdema of the vaginal walls follow a superficial laceration as well as a relaxed pelvic floor, he has ample opportunity in observing a number of the cases presenting themselves before him. While I admit that the serious train of symptoms such as cystocele, and rectocele with its attendant prolapse and subjective symptoms, is delayed in a case of simple laceration, it as certainly results from a case of relaxation. For given any case where the normal protection from atmospheric irritation and friction of the clothing is destroyed, hypertrophy and œdema are the logical result. And while those with opposite views would combat this argument with the circumstance that they have observed cystocele and rectocele in virgins who have passed the menopause, they must remember that they cite one of the rare occurrences of pathology, and might be brought to see the absurdity of their views by going still further and calling to mind the fact that cases of complete prolapsus uteri have occurred in strong, robust domestics who have the hymen intact.

The sooner we in a degree come back to a realization of the fact that a laceration of the perineum, however slight, is a pathological condition which demands interference as much as any of the other ailments of the female genital tract, the earlier shall we relieve our patients of so much suffering. There are many to day who, for a case of endometritis or salpingitis, advocate dilatation of the

[1] Manual of Skin Diseases, p. 211.

os and curetting—an operation not less serious in its results than a salporrhaphy in the hands of an ordinarily careful operator. Why, then, do we remain as extremists in our views regarding this condition, when proof is forthcoming that in this, as with nearly all others where minds have been at variance, a middle ground is our shield and haven?

CYSTICERCUS CELLULOSÆ.

By WILLIAM MOSER, M.D.,

Brooklyn, N. Y.,

Assistant Pathologist to St. Catharine's Hospital.

The hydatid ot the tænia solium is not often seen in this country. In Germany, where pork often raw or nearly so is much consumed, the parasite is by no means infrequently seen. In a discussion relative to cysticercus in the eye before the Berlin Medical Society, both Schweigger and Hirschberg were agreed that even in that country, owing to more stringent sanitary regulations, it is far less common than formerly. In England the immature tænia solium rarely finds its habitat in the eye (Nettleship). As this is its seat of predilection, we infer it is equally rare in the skin and subcutaneous tissue, brain, muscle, etc. Of course, it is admitted that all cases are not diagnosed, for the reason that the ophthalmoscopic picture is often rendered difficult by opacities in the vitreous and detachment of the retina. The latter complication is especially frequent (Schweigger), which one would naturally expect, since any foreign body or tumor (sarcoma of choroid, etc.) situated between retina and choroid only too often has this serious complication. When the view is unobstructed the diagnosis is easy, as the characteristic bluish-white vesicle seen with the ophthalmoscope cannot be confounded with any other condition. They may occur on the lid, and even in the orbit (Schweigger, Knies). In the skin and subcutaneous tissue the hydatid appears as a smooth, elastic but firm swelling. This was the condition of the tumor in a case seen by the writer. It was solitary in this case. They often occur multiple (Lewin). If the parasite be alive, the swelling has the character as stated above. If, on the other hand, the parasite be dead, the tumor is very much reduced in size and hard. Lewin, who has made and reported a number of observations, is of the opinion that they are at times mistaken for some cystic growth, lipoma or abscess. It is true, according to some observers, the sac may suppurate. In all doubtful cases the microscope is indispensable.

Cysticerci have been described by various observers in muscle. They are said to be common in the cardiac muscle and pericardium of the hog. In man, cysticercus of the myocardium or pericardium would be an interesting specimen. I would like to see one. I have never seen the hydatid in any muscle. I am inclined to believe, however, that they are apt to escape our attention. The writer well remembers, while watching autopsies in Germany, how the small white dots scattered throughout the muscle, and characteristic of the trichina spiralis, were overlooked until his attention had been called to them. We usually examine the muscular system a little hastily. These trichinæ, being calcified and consequently innocuous, are discovered accidentally at autopsies. The same statement may be applied to the cysticerci. In only two cases out of five which I saw, in which trichinæ were found in the muscles after death, was trichinosis held responsible for causing it. The cysticercus cellulosus, too, has this tendency to calcification. The scolex dies, the sac shrinks, becomes much reduced in size, and finally the whole tumor is converted into one solid calcareous mass, difficult of recognition. Such was the appearance presented in three cases of cysticerci of the brain which I saw. In two cases, it is interesting to note, the cysticercus found lodgment in the floor of the fourth ventricle; in the third case, in the lenticular nucleus. As a general rule, cysticerci of the brain are innocuous. They produce no symptoms which betray their presence. In one of the cases, however, occurring in the fourth ventricle, an internal hydrocephalus and "ependymitis granularis" were also present. As the other organs remained unchanged, the pathologist, Dr. Israel, was disposed to attribute the death in this case to cerebral compression caused by the internal hydrocephalus. The ependymitis granularis is a condition not infrequently seen in chronic hydrocephalus. It is sometimes seen in alcoholic subjects, but most frequently in the general paresis of the insane. In those cases in which the cysticercus undergoes a calcareous metamorphosis the hooklets, according to Ziegler, usually remain for a long time well preserved. The "cysticercus racemosus" described by Heller and Zenker, which has its habitat in the brain, consisting of a cluster of vesicles, usually sterile, like a bunch of grapes, has not come under my observation.

THE STERILIZATION OF THE URETHRAL CANAL.

By JAMES PORTER FISKE, M.D.,

New York.

From a theoretical point of view, when a substance or surface is made sterile it is perfectly free from microorganisms or their spores. To test a given object, to ascertain its condition, whether it be free or not from bacteria, we make cultures. If we attempt to render the urethral canal sterile, and then take a urethral sound (sterilized), introduce it into the urethral canal, withdraw, and quickly apply it to a gelatine plate, we can very soon tell whether our efforts have been successful or not. If in the tracks of the sound over the culture plate colonies of bacteria proliferate, then the urethral canal has not been rendered sterile.

Practically, we cannot readily render the urethral canal absolutely sterile, because we cannot safely use the stronger antiseptic solutions; but we can put it in such a condition that any surgical procedure may be undertaken with impunity, as regards infection from the mucous membrane itself.

The passage of the urethral sound is a procedure which I would not undertake without first attempting to sterilize the canal and tissues surrounding the meatus. I see no reason for rendering our instruments aseptic, if we do not make the field of operation also aseptic. That the meatus and surrounding surface of the glans penis is usually surgically unclean, no one will dispute, yet the sound in its passage must come in contact with these parts and ca infection down. It would be interesting to know h many cases of urethral fever can be accounted for by passage of clean instruments over parts and through canal not rendered aseptic. That we may have a con tion of profound shock follow the passage of the ureth sound, is well known, but that a form of urethral fe not due to sepsis may follow the passage of instruments, do not believe. That infection may follow dirty instruments, an unclean canal, or the flowing of urine over an abrasion produced by the sound or otherwise; but infection always precedes true urethral fever.

The passage of instruments, particularly dilators (sounds), divulsors, etc., almost invariably produces fissures or excoriations of the delicate lining membrane of the urethra, and any foci of infection existing within the canal, or any particle of sepsis carried down the urethra, are favorably placed for absorption, and each may become the starting point of urethral ulcer, lymphangitis, acute urethritis, or urethral fever. The body as a whole, and various localities in particular, have been shown to have the power of successfully resisting bacteria in certain numbers and of varying degrees of virulence. And as we reduce the number of bacteria in a given region, so we decrease the chance of germ infection, and in a region where there exists a "locus minoris resistentiæ" this is of vital importance.

To one accustomed to aseptic methods, the precautions necessary to be taken to render the passage of instruments in and through the urethra safe, are simple. A pus basin, a blunt nozzled syringe holding about one ounce, some pledgets of absorbent cotton, a warm solution of ac. boraci., four per cent., and solution of bichloride (1 to 2,000), are all that are necessary. A sterilized towel, or one soaked in the solution $HgCl_2$ (1 to 2,000), should be so arranged that the penis lays on it, and the surrounding parts are covered. The entire penis, foreskin and glans, are to be thoroughly soaked with the bichloride solution. Then take the blunt-nozzled syringe and inject the solution ac. boraci. into the urethra, repeating once. The technique of urethral injections I have already discussed in a previous number of the MEDICAL RECORD.[1] After the above procedure we can safely pass sterilized instruments in and through the urethral canal. After the passage of any instruments, especially if I suspect that any abrasions have been made, I flush out the urethral canal once more with the solution ac. boraci., and allow the patient to depart. This simple procedure is to be carried out previous to the passage of any instruments, either exploratory or for treatment, as the use of the sound in stricture, Thompson's searcher for stone, etc., and is not to be confounded with the more extensive antiseptic precautions which must precede every *bona fide* operation in this region. Instead of the saturated solution of boracic acid we may, with perfect safety and success, use a solution of peroxide of hydrogen (1 to 4), or a watery solution of Listerine in the same strength. A solution of iodoform in olive oil has been largely used, and in a measure fills the bill, both as a lubricant and antiseptic.

Many operators, immediately before any instrumental procedure, inject the canal with a solution of cocaine, and then proceed in their work, using clean instruments in many cases, it is true, but often making no attempt to render the site of the operation aseptic. If the patient understood the principles of aseptic surgery he would exclaim, "I will stand the pain, but will not tolerate the use of septic instruments or septic methods." There is no objection to the use of cocaine, but its use must be preceded by all antiseptic precautions being taken, and if the busy practitioner is pressed for time he had better discard the injections and applications of cocaine, and stick to aseptic surgery. The time and efforts expended for the prevention of pain should be applied to a better cause, the prevention of septic infection.

Some physicians will perhaps think it unnecessary to flush the canal. If the urethral canal is absolutely normal it is, but in any case where there is a pathological condition of the urethra we ought to irrigate. If the urethral mucous membrane is secreting abnormally, if we know or suspect the presence of granular patches, if there is an existing stricture, preventing as it does the free exit of discharges, irrigate by all means, and irrigate thoroughly, before the passage of any instrument. The surgeon who neglects to take this precaution in any of the above conditions, imperils the deep urethra and neck of the bladder.

If we except the catheter, it is a pretty safe rule to follow, that where there is cause to pass instruments into the urethra, there is also good reason to first flush the urethral canal. To the methodical surgeon who believes in and practises asepticism in this region, it is only a question of putting one's self to a little trouble and the expense of a little time, say seven to ten minutes, both of which he gladly bestows on his patient, realizing as he does the result of septic infection.

328 WEST FIFTY-SEVENTH STREET.

"**Drunkenness**" was the subject of discussion at a recent meeting of the Sunset Club of Chicago. Several of those present related their personal experiences with great effect.

[1] The Value of Urethral Injections in the Treatment of Acute Gonorrhœa, MEDICAL RECORD, August 26, 1893.

VIRAGINITY AND EFFEMINATION.

BY JAMES WEIR, JR., M.D.,
OWENSBORO, KY.

IN following up the chain of evolution in animal life from its inception in primordial protoplasm to its end, as we now find it, we discover that the interlinking organisms are, in the beginning, either asexual or hermaphroditic. The moneron, the lowest form of animal life, simply multiplies by division. The different elements through which propagation and generation are carried on, are undoubtedly present even in the moneron, but are not differentiated. The moneron is an organless, structureless organism, consequently asexual. The cell, on the contrary, is hermaphroditic, for it contains within itself the necessary elements for reproducing itself. The amœba is the connecting link which connects all terrene life with primitive bathybian protoplasm, and is, strictly speaking, a true hermaphrodite. Ascending at once to the sixth stage in the ancestry of man, we come to the acœlomi, or worms without body cavity.[1] These worms are phylogenetic, consequently hermaphroditic. I do not mean to say that these worms have the organs of each sex equally developed; therefore, in the use of the word hermaphrodite, I use it in its broadest sense. I simply mean that they are autogenetic. In the rhabdocœla the sexual organs appear in their simplest forms—a testis anterior to a single or double ovary. Other gliding worms have a more complex arrangement of the sexual organs, but most of them are true hermaphrodites. Next in the chain of evolutionary development, and one step nearer man, we find the soft worms (scolecidæ); from a branch of this family the parent group of vertebrates was developed. The immediate ancestor of the vertebrates was either the amphioxus (lancelet) or some other notochordate animal, whose type is now extinct. Thus we have traced hermaphroditism from the amœba to the amphioxus, from the ancestor of the parent cell to the ancestor of the vertebrates. We could carry it further, but it is unnecessary. Effemination and viraginity are due directly to the influence of that strange law laid down by Darwin—the law of reversion to ancestral types. It is an effort of nature to return man to the old hermaphroditic form from which he was evolved. It is an effort on the part of nature to incorporate the individualities of the male and female, both physical and psychical, in one body. The phenomenon of atavism is more apt to occur in feeble types than in strong, healthy, and well-developed types. Microcephalism, occurring, as it most frequently does, among ignorant, ill-nourished, and unhealthy people, is an example. Dolichocephalism and a flattening of the cranial arch, with corresponding loss of capacity in the skull—types that we see everywhere among the depraved and vicious—are other examples of this tendency of atavism to seize on weakened and unhealthy subjects. Effemination finds more victims among the wealthy and the educated than among the poor and uneducated. This phenomenon is a psychic rather than physical hermaphroditism, and is directly traceable to the enervation produced by the habits of the wealthy and unemployed. Wealth begets luxury, luxury begets debauchery and consequent enervation. Periods of moral decadence in the life of a nation are always coincident with periods of luxury and great wealth, with consequent enervation and effemination: examples of this may be found in the histories of Rome, Greece, and France. During the reign of Louis XV., examples of effemination crowded into the court and vied with the royal fop in the splendor of their raiment and effeminacy of their bearing. Psychic hermaphroditism does not occur in uncivilized or half-civilized races.[2] The reason for this is patent. Atavism finds among them no weakened and enervated subjects on whom to perpetrate this strange travesty on nature. Large cities are the hotbeds and breeding-places of the various neuroses. There, general

[1] Haeckel: The Evolution of Man, vol. ii., p. 76.
[2] Kraft-Ebing: Psychopathia Sexualis, p. 7.

paresis treads closely upon the heels of sexual neurasthenia, while the victims of hysteria and kindred ills are almost countless in their number. What wonder, then, that the offspring of such parents should be weak and neurasthenic, and fall easy victims to the thousand and one erotic fancies that beset them. What wonder that atavism here finds its richest field, and plays its strangest and most fearful pranks, sending men into the world with the tastes, desires, and habits of women, and women with all the mental habitudes of men! Juvenal wrote in scathing, searing sarcasm of the degeneracy of the Roman youth; effemination was very prevalent, and this bitter satirist advised the Roman ladies to look for men among the gladiators and peasants. The people of cities divide themselves into classes, and these classes are generally exceedingly clannish. It is not considered good form to marry out of the class to which an individual may belong, consequently no new types of individuals are added to the class.

I have shown that luxury enervates the class that indulges in it. The people of this class intermarry among themselves, and if no new blood is added, in a very few generations examples of effemination and viraginity begin to make their appearance, due to enervation and consequent psychic hermaphroditism We see daily on our streets, mild types of effemination in the cigarette smoking, soda-water-drinking young men whom the caricaturists consider their legitimate prey. The tailor-made, horsy, and loud-talking young woman is by no means infrequent—an example of mild viraginity. Effemination makes its appearance early in life. The boy likes the society of girls. He plays with dolls and, if permitted, will don female attire and dress his hair like a girl. He learns to sew, to knit, to embroider, and to cook. He becomes a connoisseur in female dress, and likes to discuss matters pertaining to the toilet. He does not care for boyish sports, and when he grows older, takes no pleasure in the amusements and pursuits of his masculine acquaintances. He prefers to spend his time with women and engage in their employments and amusements. As the change in his psychic being becomes more developed and more overpowering, he will endeavor to approach the female in gait, attitude, and style of dress. I have seen mothers guilty of incalculable harm by fostering such inclinations in their sons. They think that such perversions of taste indicate gentleness and kindness, and induce their sons to continue in the practice of them, thus assisting atavism in its baleful work. Effemination is a disease which, taken at its inception, can generally be eradicated and cured. As soon as it is discovered the boy's surroundings should be changed. His mind should be directed into new channels and his dormant boy's nature aroused. Out-door exercise and a free intercourse with companions of his own sex, should be made important factors in the treatment of an incipient effeminant. He should be carefully watched until his *vita sexualis* has been established. He should then be taught the dangers of youthful follies and indiscretions. A dandified man is always ridiculous, but when he adds to his foppery, effemination, he then becomes contemptible. Several years ago I had the opportunity of studying a pronounced effeminant. He is one of the best-known young men of a southern city, and is a leader in society. He took me to his "boudoir" and showed me his "lingerie." The words quoted are his own. His night-gowns were marvels of artistic needlework, and made by himself. His night-caps were "sweetly pretty," and one of them was a "perfect dream of beauty." On his bureau were all the accessories of a modern society woman's toilette, including rouge, powder, a complete manicure set, and numerous bottles of perfumes and toilet waters. In his wardrobe he had, displayed on forms, some six or eight corsets and chemisettes—"corset-covers" as he designated them. This man's voice and manner of speaking are decidedly feminine; all the little mannerisms and affectations of a society woman being faithfully reproduced. I understand from his associates that he is a splendid business man, and that not a breath of scandal has ever tarnished his good name. He was reared by his mother, and never associated with boys until his sixteenth year. I understood from him, that she always treated him as a girl, and consulted him in all things pertaining to her toilette. He seemed utterly unconscious of his anomalous condition, and as his business associates are gentlemen, and his intimate friends are ladies, he may drift through life without a single jar to mar the serenity of his existence.

Viraginity is by no means an infrequent occurrence, and under its influence the unfortunate victims are guilty of startling vagaries. The recent case of Alice Mitchell, who killed Miss Johnson, at Memphis, Tenn., is an example of pronounced viraginity. We see daily in the newspapers accounts of women who masquerade as men, and history abounds in like instances. The celebrated writer, Count Sandor V., was a woman who posed as a man, and who was in fact Sarolta (Charlotte), Countess V. "Among many foolish things that her father encouraged in her was the fact that he brought her up as a boy, called her Sandor, allowed her to ride, drive, and hunt, admiring her muscular energy." At the age of thirteen she ran away from school, where she had been sent by her mother, and returned home. "Sarolta returned to her mother, who, however, could do nothing and was compelled to allow her daughter to again become Sandor, wear male clothes, and, at least once a year, to fall in love with persons of her own sex."[1]

Mothers, early in life, though not from any sense of danger to their daughters, begin to eradicate the tom-boy inclinations in their female children; hence the comparative infrequency of viraginity. The congenital viragint will always remain somewhat masculine in her tastes and ideas, but her inclinations and desires having been turned toward femininity early in life, she will escape the horrors of complete viraginity or gynandry. The victim of effemination, however, is saved by no such accidental forethought. The ignorant mother fosters feminine inclinations and desires in her effeminate son until his psychic being becomes entirely changed, and not even the establishment of his *vita sexualis* will save him from effemination. An only son, who is in the least degree neurasthenic, runs the risk of becoming an effeminant under the tutelage of a loving but ignorant mother who encourages his feminine tastes and inclinations.

A young man of my acquaintance, who is an only son, is so situated. This young man devotes his entire attention to matters of the toilet. He paints his cheeks a powders his face; even his eyebrows and eyelashes a anointed with some dark-colored ointment or pomac Effemination and viraginity are more prevalent in t Old World than in the United States. The civilizati and settlement of the United States are, comparativ speaking, new. The people are, as yet, a young, stro and vigorous nation. Years of luxury and debauch have not yet brought the penalty of enervation and n rasthenia to the masses, though, in certain circles of ciety, it is becoming painfully evident that that penalty is being even now exacted. In this article I have described only mild types of viraginity and effemination. In the more pronounced types of these singular examples of atavism or reversion, the victims commit the most unheard of and the most unnatural acts. Almost every case of effemination or viraginity can be cured if recognized and treated in its incipiency. The parents should be the physicians. They should keep a watchful supervision over their offspring, and as soon as any evidences of effemination or viraginity become apparent, treatment, both physical and psychical, should at once be instituted.

Effemination has occasioned the downfall of many nations; let us guard against it with all our power. Let us train up our boys to be manly men, and our girls to be womanly women.

[1] Birnbacher: Friedreichs Blätter f. ger. Med., 1891.

Surgical Suggestions.

Hernia in Childhood.—Palliative measures are, of themselves, sufficient in almost all cases to effect a cure. To permit a child to grow up to adult age handicapped by so serious an infirmity, bespeaks culpable neglect or criminal ignorance.—Dallas.

Odontalgia.—The pain of toothache is soothed by allowing a current to pass through the painful part by pointing an electrode toward it while the patient is in communication with a static machine.—Gatchkovsky.

Galvanic Cautery should be used only by men who have taken the needful time and trouble to learn how to handle an instrument capable of so much harm.—*Journal of Balneology.*

Purulent Pericarditis.—Here operation by incision and drainage is fully justified, since its execution causes no trouble in the functions of the heart, and because it offers the only chance of safety. An incision is made in the fourth or fifth intercostal space, at a few centimetres to the left of the sternum. Drainage without washing.
—Sievers.

Mastoid Suppuration.—The technique of operating should vary with the nature and needs of the case. Usually a liberal incision close behind the auricle, free exposure of the bone, and penetration by the gouge close behind the auditory canal below the level of its upper margin and the spina supra meatum, is safest and surest to reach the antrum.—Randall.

Appendicitis.—If there is an abscess at the head of the colon with the peritoneum shut off, it should be opened, washed out, and packed. If done in time it should not have one per cent. mortality.—Price.

Fracture of the Neck of the Femur in the aged should be managed by treating the patient, and not the fracture. Leave off apparatus, use sand-bags, do everything that will make the patient comfortable and prevent bedsores.
—Allis.

Gonorrhœal Orchitis.—Paint with crystallized carbolic acid, nine grams; alcohol, one gram; several coats being applied over scrotum and course of spermatic cord. Cocaine injections will prevent pain.—Lardier.

Pneumonectomy is reported by Lawson (*British Medical Journal*). The right infiltrated apex was ligated and removed. Three months later the girl was doing well.

Bronchiectasis.—Inject into the trachea a drachm of the following:

R. Guaiacol	2 parts.
Menthol	10 parts.
Ol. oliv	88 parts.

—Stewart.

In Pelvic Abscess or repeated attacks of cellulitis due to leakage from the open end of a diseased Fallopian tube, the best interests of the patient demand early removal of the diseased tube.—Boise.

Removal of the Tongue, if contemplated for a growth of moderate dimensions, can be best accomplished by ligaturing the vessels as a part of the operation.—Haslam.

Partial Gangrene in hernia will show extension of the sloughing under prolonged manipulation. If left *in situ* the intestine may contract adhesions, and a curable form of artificial anus be produced.—Heaton.

The Gasserian-ganglion may be removed as a last resort in tic douloureux. Trephining the base of the skull through the pterygoid region is the preferable operation. The steps are: 1, the incision of the skin; 2, section of the zygoma and coronoid processes, and detachment of masseter and temporal muscles; 3, exposure of the base of the skull, and search for the foramen ovale; 4, opening the base of the skull; 5, removal of the ganglion; and 6, reposition of structures and closure of the wound.

Uterine Carcinoma.—Schultze's alcohol injection treatment is an undisputed palliative measure which should not be neglected. It not only relieves pain, but checks discharge and bleeding.—Pomoriski.

Stenosis causing obstructive dysmenorrhœa, with symptoms gradually growing worse each month, and menstruation finally stopping, and where examination shows a puckered scar instead of an os uteri, is best treated by introducing a duckbill speculum, fixing cervix with volsella, and incising with sharp knife through scar which represents the os.—Herman.

Hernia in children should be operated upon (MacEwen's method) if not cured by the careful and continuous use of a truss for one year.—White.

Œsophagotomy.—Where foreign bodies present angular or sharp surfaces, abstain from attempts at extraction and proceed at once to operate.—Cahier.

Gummy Syphilides of the lower extremities extend rapidly in those who neglect personal cleanliness. After poulticing, apply

R. Nug. de Vigo,	
Styrax	ā 10 grams.
Vaseline	50 "

—Besnier.

Contracted Meatus is alone sufficient to cause urethral inflammation by reflex irritation, and when such a condition obtains, permanent relief cannot be expected without complete division of the orifice.—White.

Indications for Intubation.—In the early stages of croupy children; in the cases of diphtheria where the membrane is principally in the fauces: in cases of dyspnœa in children dying of diphtheria, where the parents will not consent to a tracheotomy.—Burrell.

Tetanus is much more frequent after gunshot wounds than after other injuries; and after several of the battles of our late war the statistics show a very large prevalence of tetanus, because the patient lay exposed for an unusual length of time in the heat of the sun, the nervous system became thoroughly exhausted, and absorption of dirt germs ensued.—Cheever.

Symblepharon Treated by Snellen's Method.—Mr. Priestley Smith showed a boy upon whose left lower eyelid he had operated for symblepharon by Snellen's method. The adhesion between lid and globe, which was the result of a burn, having been freely divided, reunion was prevented by the interposition of a thin flap of skin obtained from the outer surface of the lid. The flap was pushed through a sort of buttonhole in the lid, and thus brought into position between lid and globe without severing its pedicle. The pedicle was severed later.

The Ordinary Fracture of the lower extremity of the radius usually requires no splint, and should be dressed with a wristlet of adhesive plaster or bandage. When a splint is required, a narrow, short dorsal splint, fixing the wrist, is all that is necessary.

Fractures of the lower extremity of the humerus of ordinary severity are, as a rule, more successfully treated in the extended than in the flexed position, because the "carrying function" is less liable to be impaired.—Roberts.

Small Tympanic Perforations, Dr. Harris says, may be positively diagnosed by blowing finely pulverized boracic acid against the drum until it is coated. Examination a few hours later will show a dark spot where the secretions have passed through.

Progress of Medical Science.

The Bacteria of the Respiratory Passages.—The respiratory passages being freely in communication with the external air on the one part, and with the saliva on the other, are naturally continually exposed to microbic invasion. According to Pettenkofer, among all the various ways by which pathogenic organisms can gain entrance to the animal organism, the lungs occupy the chief position (*Medical Press*). In the normal state, that is to say, when the integrity of the passages is complete, no microbic infection takes place, but the case is different when any lesion of the mucous membrane exists. In the nasal cavities of eighty-one persons examined, the mucus obtained therefrom contained pathogenic as well as non-pathogenic bacteria. Among these persons were six medical men engaged in laboratory work, eight domestics, four soldiers, and twenty-eight convalescents. There appears, therefore, to be no doubt that even in the case of the healthiest men the nasal fossæ become as it were the storehouse of a large number of microbes of various species, some of a virulent character, which are ready at the first opportunity to create mischief in the respiratory passages. Besser has studied the bacteria found in the larynx and bronchi, and for this purpose he examined the bodies of many persons shortly after death. In the mucus of the larynx in five cases he detected the streptococcus pyogenes; in the same cases the staphylococcus dore was present three times, and the micrococcus albus liquifaciens four times. So far as the normal bronchial mucous membrane is concerned, the number of bacteria is not so considerable In ten cases examined after death the streptococcus pyogenes was found twice, the diplococcus of pneumonia thrice, the staphylococcus aureus thrice, and the bacillus of Friedlander once. Thus there is evidence to show that the microbes of pneumonia and of suppuration can survive in the bronchial secretions without causing any pathological changes in the lungs. The question then arises how it is that these microbes are able to display their virulent effects. Undeniably the influence of cold in the majority of cases has much to do with this result. From the inhalation of cold air bronchitis is produced, and with the sudden chilling of the body while in a state of perspiration nutritional changes are caused, which in each case afford the microbes the opportunity of asserting their virulence.

Influence of Extirpation of the Gall-bladder on Digestion.—As is well known, the bile, which is so essential for the digestion of fat, is normally poured into the small intestine only periodically, viz., at the time when there is the greatest demand for its presence. When, however, the gall-bladder has been extirpated there is presumably a constant trickling of bile over the mucous membrane of the intestine, consequently affording only a small amount at the time when intestinal digestion is at its height. What the effect of this may be upon digestion, especially the digestion of fat, has never been determined. Küster has indeed intimated that in his opinion total extirpation of the gall-bladder would give rise to general disturbances of the system, such as follow, for example, total extirpation of the thyroid. As, however, cholecystectomy is an operation occasionally called for, knowledge of the probable results to follow are especially desired, and Rosenberg has attempted to obtain experimental evidence of the effect of the removal of the gall-bladder on the digestive processes of the intestinal tract. His experiments were conducted on a dog of 10.3 kilos. body-weight, the animal being confined in a suitable cage and fed upon a weighed diet of known composition. After the animal had been brought into a condition of equilibrium the urine and fæces were analyzed for three distinct periods of four days each, the amount of fat and proteid matter absorbed under these normal conditions being thus ascertained. The gall bladder was then entirely removed by making an incision along the right mammillary side, only a small piece of the cystic duct being allowed to remain. The wound healed quickly, and after three days of fasting the animal was allowed to eat, and on the seventh day after the operation was put upon his former diet. Shortly thereafter the urine and fæces were again analyzed for three periods of four days each, the diet being the same as before the operation. The following table shows the results obtained:

	Before the Operation.			After the Operation.		
	I.	II.	III.	IV.	V.	VI.
Absorption of nitrogen in per cent.	93.75	95.40	95.55	93.50	95.14	95.05
Fat in per cent.	98.66	98.18	98.53	98.04	98.53	97.69

It is thus evident that so far as the ultimate result is concerned, the digestion and absorption of both proteids, or nitrogenous foods, and fats is not in the least affected by extirpation of the gall bladder. In order to make sure that the bile, after the operation, did flow constantly over the mucous membrane of the intestine, the animal was killed after fasting twenty-four hours, and the parts examined. As a result, it was found that the portion of the cystic duct remaining, together with the point where it was joined to the hepatic duct, were widened to the thickness of an ordinary lead-pencil, while the ductus choledochus was normal throughout, without the slightest appearance of widening. Further, the entire mucous membrane of the intestine was covered with yellowish brown bile, thus showing that the bile did flow continuously into the intestine. Hence, it would seem safe to conclude that extirpation of the gall-bladder, followed as it must be by a continuous flow of bile through the intestinal tract, is without influence on digestion.—*Dietetic Gazette.*

Removal of Cancerous Inguinal Glands.—Dr. Ruprecht calls attention to the necessity of a radical removal of the inguinal glands in cases of carcinoma of the umbilicus, the penis, the vulva, the anus, and the lower extremity, and also in many instances of cutaneous sarcoma on the thigh. This practice he has carried out during the past ten years in every case of cancer in the abovementioned regions, in which a prolonged operation was not contraindicated by debility of the patient, or advanced age. In the groin, as in the armpit, in cases of cancer of the breast, the glands, it is held, should be removed, even though not appreciably enlarged. In cases of cancer either on the right or the left side, only the corresponding inguinal glands are removed, but in cases in which the primary disease is seated in the median line of the body, the author clears out both groins. The operation, like that for removal of the axillary glands, is a extensive one. A skin incision is made from the spine of the pubes to the antero-superior spine of the ilium, and a second is carried downward from the middle of this along the course of the femoral vessels. The skin is then separated from the subjacent soft parts as far as the aponeurosis of the external oblique muscle above, the fascia lata on the outer side, and the adductor muscles on the inner side. The triangular mass of fat and glands thus circumscribed is then carefully detached from the deep fascia by using as far as possible a blunt instrument. In the course of the dissection it is necessary to divide the saphenous vein. It is often necessary to remove the fat and glands from the fossa ovalis after division of the falciform process, and also to reach deep-seated glands by incising Poupart's ligament.—*Centralblatt für Chirurgie.*

Vicarious Symptoms.—*The Wife:* There is a prescription that the doctor left for you to day when he called and found you out.

The Husband: How did he know what to give me?

The Wife: He said that from my appearance and symptoms he knew you were suffering from chronic dyspepsia.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, September 16, 1893.

THE EDUCATION OF EPILEPTICS.

In a paper upon this subject, read before the Social Science Association in Saratoga, September 5th, Dr. Louise Fiske Bryson calls attention to the fact that two well-defined errors exist in the public mind concerning epilepsy. One is that all epileptics are insane. The other, that very few persons have epilepsy. In point of fact, epilepsy is a wide-spread disorder. It is calculated that one person in five hundred is thus afflicted. In the United States alone there are in the neighborhood of one hundred and thirty thousand epileptics, and over twelve thousand in the State of New York. They are everywhere in our midst. There are epileptic doctors, clergymen, bookkeepers, dressmakers, masons, and telegraph operators, who practise useful pursuits in spite of adverse circumstances. That all epileptics are insane, or about to be, or carry insanity around as a concealed weapon, is not true. The proportion of insane epileptics is really very small, much less than ten per cent., taken at the utmost (Peterson).

The epileptic child is always a sick child. He is different from others—not insane, but sick and subject to periods of disablement all his life. This should be taken into account from the start. Afflicted with a horrible malady, every effort should be made to render him agreeable and useful to his fellow-creatures. His whole future may depend upon his power of pleasing and being pleased. Too often dreamy, suspicious, irritable, uncertain, and subject to fits of violent temper that make him "gey ill to live with," the first lesson for the unfortunate child is self-control and self-effacement. Outbursts that in the healthy might occasionally be overlooked, should always be calmly and firmly suppressed. The impulse to violence of speech and conduct may last a lifetime. The power to control it can be acquired. While epilepsy does not necessarily lead to mental and moral degeneration, it is quite possible that the patient and the patient's family must exercise an ever alert intelligence if they would be sure that it does not efface some of the finer manifestations of mind. Epileptics who have been able to keep their place in the world in spite of their great disability, no doubt owe their success largely to the wise training of unsentimental parents, who early formed in them habits of order and self-control.

As the right training of mind is one source of physical vigor, education in its widest sense is the chief hope of the epileptic. What, then, should be its aim, its scope? The same as for a well child, the only difference being the necessarily modified application of methods. Hours must be shorter, and the intervals between tasks and lessons longer. Like all other children, the epileptic should begin his education in the kindergarten, among companions of his own age, where self-control, self-reliance, and the value of mutual concessions are learned in a perfectly natural and spontaneous way. The kindergarten is a system of scientific sense training, and capable of substituting correct habits of observation for the deadly introspection so common in nervous disease. To be practical, after the kindergarten, primary and grammar school age (the years devoted to the acquisition of tools and standards), education should concern itself with the universal interests that will endure when everything else fails and is outgrown. Of these permanent interests, literature, history, social economics, and the objective sciences are the chief, seasoned with something of art and a taste of foreign languages. Physical education is of supreme importance, since without some physical imperfection, either structural or chemical, epilepsy could not exist. The necessity of outdoor sports is at once apparent. Like others who are nervously weak, the epileptic must ever keep in mind two words that should always be joined as closely as the Siamese twins: moderation, exercise. With these they need not fear the uses of many legitimate pleasures, and even occasional irregularities in eating and sleeping.

Following school and college days comes special technical training for some chosen career. Though many attractive callings are permanently closed to the epileptic, since consciousness may leave him at any moment and without warning, the things that remain are many and consoling, and the trained will always find the way. As encouragement and incentive, it must ever be remembered that epilepsy and genius may co-exist. Dr. Peterson calls attention to certain well-known historical characters in whom the two have been united. While it may not be given to every epileptic to describe his own sufferings as does Dostojewsky in his novel "The Idiot," or to delight the world with music as did the epileptic Handel, or with comedy as did Molière, or with poetry as did Petrarch, or with military exploits as did Cæsar and Napoleon, or with religion as did Mahomet and St. Paul, it is still possible for him to exercise all of his own capabilities for his own support and for his own welfare and happiness.

To secure right conditions for the exercise and training of these capabilities, is the office of education—first of the public, then of the epileptic.

A Discussion on Cholera.—At the request of the Indian Government, the organizing committee of the Eleventh International Medical Congress has decided to establish a subsection of the Section of Hygiene, to discuss the whole subject of Asiatic cholera, to study its origin, the means of arresting its diffusion, and its treatment.

A Case of Poisoning by Balsam of Peru is reported by Dr. Lohaus. The subject was a nursing infant, and was poisoned by the balsam used by the mother for sore nipples.

THE PAN-AMERICAN MEETING.

The meeting of the Pan-American Medical Congress held recently at Washington, marks an era in the history of medicine in the Western Hemisphere, in that were brought together for the first time the representative medical men of the two Americas. We are pleased to note that the arduous endeavors of the accomplished and energetic secretary-general and other prominent officers of the Congress have been rewarded by such a complete success as to numbers in attendance as well as interest in the topics presented. The attendance, despite many adverse circumstances which obtain at this season of the year, was remarkably good, and the harmony of spirit and systematic working of the different parts of the complex organization does credit to all concerned. It was a difficult and delicate task, on the part of the organizers of the movement, to give each district its proper recognition and representation, but so far as can be seen no one was neglected, while the aggregate number of active participants was unusually large. It was eminently fitting that the President of the United States should open the Congress by a cordial god-speed for its beneficent work in the interchange of views calculated to minister to the health and consequent prosperity of two great countries. Although the attendance from the Eastern States was not as large as might have been desired, it was sufficiently representative of American medicine to give an idea to our foreign visitors of the trend of American thought and the animus of American work. Nor will we, in turn, be less impressed with the earnestness of purpose, honesty of endeavor, and sound practical suggestions of our distinguished confrères.

This meeting will doubtless be the beginning of a better understanding than ever between the two Americas, which, epidemiologically speaking, are oftentimes so closely connected in a common interest for self-protection against two of the most wide-spread and destructive of diseases. There was, we are gratified to note, a proper disposition to take the initiative in the way of formulating rules of action in times of emergency, by the establishment of uniform systems of quarantine and such proper health regulations as would best guarantee against the spread of pestilences. The other scientific work was fully up to the standard of the larger conventions, allowance always being made for the multiplicity of miscellaneous subjects and the necessary limitation of time in these presentations. We trust, however, that we have given our readers a full digest of the proceedings in the exhaustive reports which appear in the present issue, and which will be continued in future issues. We thus place on permanent record one of the most remarkable and, we hope, most edifying medical conventions of the year.

CŒLIA AND LAPARA.

Our friends the gynecologists are receptive and progressive. They drop the ovaries and take up the tubes; they leave the tubes and smite the appendix or loosen up the clitoris; they abandon the much prescribed douching for "whites," and simply wipe and clean and do an "antiseptic toilet."

We notice that recently there has been a sudden change in gynecological nomenclature from laparotomy to cœliotomy. In one week three notices of operations, from as many hospitals of this city, contained an announcement of four "cœliotomies." We are quite willing to admit that cœliotomy is the better word, though it is only six years old, but this is not very apparent at first sight. Cœlia means the abdomen or belly, and so does lapara. But cœlia also means any cavity of the body, including the ventricles of the brain, so that by cœliotomy one may mean the opening of the brain, thorax, or abdomen. The gynecologist should be reminded that there are other cavities than that which he manipulates so skilfully. Besides, there have been combined with the word "lapara" over twenty other words, making compounds which have come into more or less use. There will have to be a readjustment of all this, which it seems to us must be confusing and unnecessary.

TEN TESTS FOR DEATH.

It is the rarest thing in a physician's experience to be placed in any doubt as regards whether a person is dead or not. The cessation of breathing, the absence of audible heart-beat, and the physiognomy of the patient are enough. Every now and then, however, we are called upon to give some absolute test of death which is not connected with the heart-beat or the respiration. One of these criteria is the so-called "diaphanous test," which consists of an absence of the translucence seen in living people when the hand is held before a strong light with the fingers extended and in contact. An English physician relates in the *Lancet* an interesting experience with this test.

He was called to see an old lady who was believed to be dead, but whose countenance looked natural and life-like, the eyes being open. The family, being extremely anxious, urged that all the tests of death be applied, and this was done in the following order:

1. Heart-sounds and motion entirely absent, together with all pulse movement.
2. Respiratory sounds and movements absent.
3. Temperature of the body taken from the mouth the same as that of the surrounding air in the room, 62° F.
4. A bright needle plunged into the body of the biceps muscle (Cloquet's needle test) and left there, shows on withdrawal no sign of oxidation.
5. Intermittent shocks of electricity at different tensions, passed into various muscles and groups of muscles gave no indication whatever of irritability.
6. The fillet test applied to the veins of the arm (Richardson's test) causes no filling of the veins on the distal side of the fillet.
7. The opening of a vein to ascertain whether the blood has undergone coagulation shows that the blood was still fluid.
8. The subcutaneous injection of ammonia (Monte Verde's test) causes the dirty-brown stain indicative of dissolution.
9. On making careful movements of the joints of the extremities, of the lower jaw, and of the occipito frontalis, rigor mortis is found in several parts.

Thus of these nine tests, eight distinctly declared that death was absolute, the exception, the fluidity of the blood, being a phenomenon quite compatible with blood

preternaturally fluid and at a low temperature, even though death had occurred.

10. There now remained the diaphanous test, which we carried out by the aid of a powerful reflector lamp yielding an excellent and penetrating light. The writer says: "To our surprise the scarlet line of light between the fingers was as distinct as it was in our own hands subjected to the same experiment. The mass of evidence was of course distinctively to the effect that death was complete; but, to make assurance doubly sure, we had the temperature of the room raised and the body carefully watched until signs of decomposition had set in. I made a visit myself on the succeeding day to assure myself of this fact."

This experience shows that the diaphanous test is not a trustworthy one.

A CHINESE DOCTOR MAKES A PLEA.

Dr. Tom She Bin, Chinese physician, of Los Angeles, Cal.; writes to the *Sun* in behalf of himself and his countrymen who want to practise medicine. He says:

"In many States we are not permitted to practise medicine unless we pass examinations prescribed by the laws of those States; we are not supposed to know the American medical systems upon which the examinations for practice are based; and notwithstanding we are the masters of an older and superior system; notwithstanding we, when given a chance, cure ninety per cent. of the alleged incurables who for years have tested the inefficiency of Western medicines and skill; notwithstanding we possess honorably earned diplomas, the result not of two or three years' study, but of thrice that time—diplomas whose genuineness is attested by the officials of our Government: we are, in defiance of solemn treaty stipulations of the United States, which cover our business and in any other country would protect us in our cure of disease, driven from the practice of medicine."

Dr. She Bin says many other things to show that he and his countrymen are unfairly used. Perhaps he is right in some respects, but as to medicine he is wrong.

The States require of the Chinese, before they can practise medicine, only the same thing which is required of all others, natives and foreigners. The fact that he has studied Chinese medicine for many years does not help him, because, according to the standards of all civilized countries, this is not medicine, but a mixture of voudooism and stupid traditions.

Last Year much joy was given to the Parisians by a man with a musical anus. This year medicine supplies the curiosity. At the close of the Congress for the Advancement of Science the members of the Section of Medicine had a banquet. At dessert the "venerable Dr. Schiff, of Geneva, who presided," entertained the company by playing the "Marseillaise" with the abductor muscles of his feet. Strong rhythmic contractions produced a sound audible for two or three metres. He is said to be the only possessor of this accomplishment in society, which, however, does not prevent him from being a gallant gentleman and a scholar—*Au contraire!*—*Cor. Boston Medical and Surgical Journal.*

News of the Week.

Army Medical Appointments.—The following nominations have been made by the President: Major H. R. Tilton, Surgeon, to be Lieutenant-Colonel and Deputy Surgeon-General. To be Assistant Surgeons with rank of First Lieutenant: A. N. Stark, of Virginia; Charles Lynch, of New York; J. S. Culp, of Pennsylvania; E. L. Munson, of Connecticut; Charles B. Flagg, of South Carolina; J. M. Kennedy, of South Carolina; G. C. M. Godfrey, of Ohio; and W. F. Lewis, of North Carolina.

The Human Body used as a Medicament.—The leaders of the late anti foreign movement in China stirred up their emissaries to hatred of the foreign dwellers in their midst by various false accusations. Missionaries were charged with bewitching women and children, and murdering them for the sake of their hearts and eyes. According to Dr. Macgowan, who has lived in China for years, these charges are far from preposterous; for in that country various portions of the human frame are credited with therapeutic properties. In the only Chinese authoritative materia medica thirty-seven remedies of the kind are given. Human blood, taken into the system from another, is thought to strengthen it. Of course, this idea is not purely Chinese, as Western medicine has its transfusion of the blood of others as a last resource in extreme hemorrhage. But other Chinese remedies are not elsewhere recognized as efficacious. Thus, human muscles are supposed to be a good remedy in consumption, and children mutilate themselves to administer their flesh to sick parents. This treatment, too, is especially frequent among the *literati*. A graduate, finding "the snipping of the skin from his own arm too painful, seized a hatchet and cut off a joint of one of his fingers, which he made into broth mixed with medicine, and gave to his mother." The recipient must be kept in absolute ignorance of the potion thus prepared, while the operation is never performed for an inferior, as by a husband for a wife, or by a parent for a child. There is, consequently, a demand for portions of the human body, which command a certain price; and this fact tempts men to murder others that they may obtain the money which will be paid for the portions in question.

Increase of Morphiomania in Paris.—In 1883, according to an estimate made by M. Foville, the number of victims of morphiomania in Paris was 40,000; now M. Dubut de Laforêt puts the number at 100,000.

Arkansas State Lunatic Asylum.—Dr. P. O. Hooper, the medical superintendent of the Arkansas State Lunatic Asylum, has been forced to resign, as it was impossible, in consequence of political interference, to obtain competent assistants. Dr. Hooper has held office since the foundation of the Asylum.

Special Tour of Foreign Delegates to the Pan-American Medical Congress.—The foreign delegates to the Pan-American Medical Congress, in charge of Dr. S. S. Adams, of Washington, Chairman of the Committee of Arrangements, visited New York on Monday last, and were the guests of Dr. Lewis A. Sayre. A visit was made to Bellevue Hospital and the New York Academy of Medicine. A luncheon was given at the City Club, where speeches were made by Dr. August Comeau, of

Hayti, Dr. G. Mendizal, of Mexico, Dr. Reginald H. Sayre, Dr. George F. Shrady, of New York, and Mr. Ernest Hart, of London, editor of the *British Medical Journal*. The guests then visited the New York Cancer Hospital after a drive through Central Park, and, returning, inspected the Presbyterian Hospital. A portion of the delegation visited quarantine, and were the guests of Dr. W. T. Jenkins, Health Officer of the Port of New York. The delegation visited Boston on Tuesday and Wednesday, Saratoga on Thursday, Niagara Falls on Friday, and will spend Saturday and Sunday in Detroit, Monday in Cincinnati, and will arrive at Chicago on Tuesday next, where the members will separate for home

The Seventh Annual Meeting of the American Orthopedic Association will be held at St. Louis, Tuesday, Wednesday, and Thursday, September 19, 20, and 21, 1893. The sessions will be held in the lower hall of the College of Pharmacy, 2110 Lucas Place, at 9 A.M. and 2 P.M. daily. At noon, on Tuesday and Thursday, the Association will go into executive session. The annual dinner will be held Wednesday evening, at 8 o'clock.

An Army Medical Board will be in session at Washington City, D. C., during October, 1893, for the examination of candidates for appointment to the medical corps of the United States Army, to fill existing vacancies. Persons desiring to present themselves for examination by the board will make application to the Secretary of War, before September 15, 1893, for the necessary invitation, stating the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from whence they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates based on personal knowledge, from at least two physicians of repute, as to professional standing, character, and moral habits. The candidate must be between twenty-two and twenty-eight years of age and a graduate from a regular medical college, as evidence of which his diploma must be submitted to the board. Further information regarding the examinations may be obtained by addressing the Surgeon-General, United States Army, Washington, D. C.

There is Great Newspaper Indignation over the alleged misconduct of two physicians lately assistants at the Flatbush Insane Asylum. It is asserted that one of these gentlemen placed a lighted cigarette between the lips of a corpse upon which they were making an autopsy, while the other danced around it. It would be wiser to find out the facts before the local editors get too much excited. The tale seems to be a very highly colored one.

A New Medical School in Boston.—The trustees of Tuft's College have decided to establish a medical department. The new school will be located in Boston, and will be opened next October to men and women on the same footing. Albert Nott, M.D., is the Dean, and Charles P. Thayer, M.D., the Secretary.

Western Reserve Medical School.—Professor Gad, of Berlin, has been appointed professor of physiology in the medical school of the Western Reserve University, O. The required school term each year hereafter will be eight months. The new professor, Dr. Gad, ranks among the leading physiologists, and has just written a text-book which has been very highly commended, especially for the thoroughness of its chapters on the nervous system.

Professor Czerny has sent a contribution of twenty dollars to the Gross Monument Committee, as a mark of his "admiration for the man and the surgical work which he has done."

The Progress of Cholera.—The report of the United States Consul at Nantes, France, which reached the Marine Hospital Service this morning, shows that cholera is on the increase there to an alarming extent. For the week ending August 26th there were 73 cases and 36 deaths, not including those treated at the various hospitals. The previous week showed only about 50 cases and 15 deaths. Surgeon General Wyman, of the Marine Hospital Service, received a cablegram from United States Consul Rosenthal, at Leghorn, Italy, saying that there was cholera at that place. Without specifying the period of time, he says that there were 27 cases, 5 of which resulted fatally. On Saturday and Sunday, according to the returns of the Imperial Board of Health, only 4 fresh cases developed in all Germany, and none of these was in Berlin. A death from Asiatic cholera was reported September 11th at Retford on the Idle, county of Notts. Another death from Asiatic cholera has occurred at Rotherham, in the West Riding of Yorkshire. The physicians' report as to the two deaths at Retford, county of Nottingham, confirms the statement that they were caused by Asiatic cholera. A death that recently occurred at Gainsborough is now declared to have been due to the scourge. There has been a severe outbreak of cholera in Leghorn, in a dirty quarter of the town named Venuzia. In this district, September 11th, 265 cases and 7 deaths were reported. The record in other infected places for twenty-four hours is as follows: Naples, no new cases; Cassino, 4 new cases, 1 death; Palermo, 3 new cases, 4 deaths. Cholera returns from Constantinople for September 12th show 14 new cases and 5 deaths. A bacteriological examination was made into the cases of two men who died there, September 12th. Both are believed to have died of Asiatic cholera.

Death of Dr. Graily Hewitt.—We regret to have to announce the death, at the age of sixty-five, of Dr Graily Hewitt, for many years professor of obstetri medicine in University College, London, and obstetri physician to the hospital. Dr. Hewitt's contributior to the special branch to which he devoted his life wer numerous and important, and his personal characte caused him to be much beloved by students and co leagues alike. We hope to publish a full obituary notic at an early date.

Medical Education in the United States.—*Polk's Medical Register of the United States for 1893* contains the names of more than 105,000 practitioners, including "'paths" of every variety. Of the 137 lawfully established colleges in the United States and Canada. 23 now require four courses of instruction of not less than six months each; 23 require four or more years of study and three courses of not less than six months each; 55 require three or more years of study and three terms of not less than six months each. Of the remaining 36, all but 7 have announced a minimum requirement of three courses of instruction before candidates are admitted to the final examination. Nearly

every medical college in the United States now requires clinical instruction, laboratory instruction in chemistry, toxicology, the analysis of urine, normal and pathological histology, bacteriology, pathology, and hygiene. More than ninety per cent. of the regular colleges in the United States now require preliminary education equal to or better than that required in high schools of the first class.

American Public Health Association.—The twenty-first annual meeting of this Association will be held in the Art Institute Building, Chicago, October 9 to 14, 1893. In connection with the World's Congress Auxiliary, it is proposed to make this meeting an International Congress of Public Health, and the preliminaries have been conducted with this end in view. The meeting will be held in sections, and papers will be classified accordingly.

Onychophagy is the name given by a French physician to the morbid habit of nail-biting. He finds it very common among French school-girls—61 out of 207 in one school. Are the deformed finger-ends and nails so commonly seen a result of the custom?

Reviews and Notices of Books.

Naphey's Modern Therapeutics, Medical and Surgical, including the Diseases of Women and Children. Ninth Edition. Edited by Allen J. Smith, M.D., Professor of Pathology, University of Texas, and J. Aubrey Davis, M.D., Assistant Demonstrator of Obstetrics, University of Pennsylvania. Philadelphia: P. Blakiston, Son, & Co. 8vo, pp. 1112.

The general plan of this well-known work is consistently followed out in the present volume and gives the reader an amount of practical knowledge of the numerous subjects touched upon which is not only well arranged but tersely presented. The number of formulas presented from the leading authorities in the different branches is remarkable and bears evidence of very careful selection. It is a capital work of its kind, and will prove, as it has done before, an excellent and suggestive aid to the practitioner.

Clinical Lectures on Abdominal Hernia, chiefly in Relation to Treatment, including the Radical Cure. By William H. Bennett, F.R.C.S., Surgeon to St. George's Hospital, etc. London and New York: Longmans, Green & Co. 1893. 8vo, pp. 225.

This volume is made up of revised clinical lectures on the subject treated, which were delivered in St. George's Hospital, London, and afterward published in *The Lancet*. In their new form they present the reader with a number of interesting facts connected with differential diagnosis and much of necessary detail in the perfection of radical treatment. The author is in favor of the simpler radical operations and advocates the invagination of the sac as the preferable one when it can be performed. His remarks on differential diagnosis are admirable, and will be read with great interest by everyone liable to meet a hernia with an obscure history. The diagrams in the work are well made and answer their purpose most satisfactorily.

Influenza. Its Pathology, Symptoms, Complications, and Sequels; Its Origin and Mode of Spreading, and its Diagnosis, Prognosis, and Treatment. By Julius Althaus, M.D., M.R.C.P. Lond., Senior Physician to the Hospital for Epilepsy and Paralysis. Second Edition. London: Longmans & Co. 1892.

So much has been written upon the subject of influenza since the late epidemic began, that, in preparing a second edition, the author has an extensive journal literature to go over, and this has undoubtedly been of much assistance in making this account of the disease in its varied aspects as complete as it is. The thought naturally comes into one's mind on first picking up this work, What circumstances have led a man like Althaus to produce a work upon the grip? Few pages have to be read, however, before one is forcibly reminded of the vast importance of the disease in its relation to the nervous system, in its onset and clinical features as well as in its sequelæ. In the chapters devoted to the nervous forms, to the post-grippal psychoses and diseases of the brain and membranes, spinal cord and peripheral nerves; to the sympathetic system and to general neuroses, the author is especially felicitous, while no portion of the subject has been neglected. Literary references are quite copious, and the index of authors takes up several pages. There are three hundred and sixty-three pages of very readable matter, and one can find much valuable information presented in an attractive way.

Pocket Dose-Book. Edited by John Edwin Rhodes, M.D. Chicago, Ill.: Sharp & Smith. 1893.

This vest-pocket edition contains a complete posological table of old remedies and the new ones of established value. The doses are given in both apothecaries' weights and measures and in the metric system, with easy rules for changing from one to the other. The book also contains rules for artificial respiration and treatment of asphyxia, a table of poisons and their antidotes, etc.

A Text-Book of the Theory and Practice of Medicine. By American Teachers. Edited by William Pepper, M.D., LL.D., Provost and Professor of the Theory and Practice of Medicine, and of Clinical Medicine, in the University of Pennsylvania. In Two Volumes. Illustrated. Volume I. Philadelphia: W. B. Saunders. 1893.

This new work is apparently intended as a compromise, in size as well as in thoroughness of treatment of the separate articles, between the encyclopedic treatise of medicine and the ordinary one-volume text-book. This first volume contains forty-five articles, averaging twenty pages each, written by six contributors. The subjects treated of are hygiene, the infectious diseases, and nervous, muscular, and mental diseases. Some of the articles are rather unsatisfactory in their brevity, and others are longer, in proportion to the size of the treatise, than the importance of the subject demands; but, apart from this unevenness, the work is good. The articles are practical and up to the times, and, moreover, the authors are all well-known teachers of medicine who are entitled to speak with an authority that commands respect. This work, like the three-volume one published, under the same editorial management, by Lea Brothers & Co., is, we understand, sold by subscription only, a method of sale which we should think would interfere with its use as a students' text-book. We presume its distinguished editor has not undertaken this work without the consent of Messrs. Lea, publishers.

The Year-Book of Treatment for 1893. A Critical Review for Practitioners of Medicine and Surgery. Philadelphia: Lee Brothers & Co. 1893.

This is the ninth edition of this excellent annual. The review of therapeutic progress embraces the second half of 1891 and the first half of 1892. Two new articles, "Anæsthetics" and "Public Health and Hygiene," have been added to this edition. This Year-Book is destined to retain its popularity for many years.

The Chronic Disorders of the Digestive Tube. By W. W. Van Valzah, A.M., M.D. New York: J. H. Vail & Co. 1893.

This little book brings nothing new nor original, and confounds new scientific problems with obsolete theories. The author speaks of atrophy of the stomach, or of cases with anacidity, and postulates a thorough examination of the blood, urine, and fæces as the best help for diagnosis.

Society Reports.

Pan-American Medical Congress.

First Meeting, Held at Washington, D.C., September 5, 6, 7, and 8, 1893.

(Special Report to the MEDICAL RECORD.)

(Continued from p. 346.)

SECTION ON OBSTETRICS.

GILES S. MITCHELL M.D., EXECUTIVE PRESIDENT; HUGH HAMILTON, M.D., AND JOHN J. CASTELLANOS, M.D., SECRETARIES.

FIRST DAY, TUESDAY, SEPTEMBER 5TH, AFTERNOON SESSION.

The President's Inaugural Address.—Parturition, the President of the section said, cannot in different races and in different countries so widely differ, hence the means of aiding it should not be so varied. He was convinced that such a meeting as the one being inaugurated would be more potent in diffusing a more just and mutual appreciation of our knowledge and practice than volumes of literature, and work beneficial results which would be felt throughout the great republic of science. We were here to express collective judgment upon controverted points. Certain great principles had been grasped which seemed unlikely to undergo change, but the mode of application of those principles was susceptible of infinite improvement, and each step in advance meant probably the saving of many lives.

"Medicine," Lord Bacon had said, "has been a science more professed than labored, yet more labored than advanced; the labor having been, in my judgment, rather in a circle than in progression. For I find much iteration, but small addition." Especially was this true of obstetrics until the last two decades, since which time the progress had been extraordinary.

In 1847 Semmelweiss had clearly indicated the true nature of puerperal infection, but his voice was not heeded until Lister utilized the researches of Pasteur and became the father of antiseptic surgery. The enthusiasm with which the German school embraced the antiseptic plan soon led to abuses, which were followed by serious consequences. Then Winckel, Breisky, and Gusserow inaugurated the present aseptic or prophylactic plan.

The most famous teacher of obstetrics in France to-day had introduced the forceps.

Allusion was made to the development of Cæsarean section and its modifications, to the renewal of symphyseotomy with its wonderful results, to the prevention of tetanus and ophthalmia neonatorum by asepsis or antisepsis, and to the prevention of much suffering on the part of mother and child by the practice of aseptic principles in general.

The consensus of opinion of this section ought to go very far toward settling many disputed questions, such as how much pressure and moulding the fœtal head could be subjected to without permanent damage? When is delivery by turning preferable to forceps? The limitations and field of symphyseotomy, Cæsarean section, Porro's operation, and the induction of premature labor?

In conclusion, Dr. Mitchell extended his personal thanks to the Secretaries, Drs. Hamilton and Castellanos, for their untiring efforts in behalf of the section.

The Hemorrhages of Pregnancy; Their Management.—DR. JOHN O. POLAK, of New York, read the paper. Hemorrhages due to rupture of the uterus and to extra-uterine pregnancy were left out of consideration. Others occurring ante-partum were: (1) Bleeding as a symptom of miscarriage; (2) placenta prævia; (3) accidental hemorrhage from the partial separation of the normally placed placenta and ectopic gestation, post-partum hemorrhage from atonicity of the uterus, and lacerations of the cervix, vagina, and vulva. Hemorrhage as a sign of miscarriage, when very slight, could be controlled by rest in bed, suppositories of morphia and atropia, drachm doses of fluid extract of viburnum, or pills containing four grains of the solid extract. He could report thirty-two cases treated in this way, averting abortion. In more severe cases, when abortion was inevitable, everything should be made aseptic, and the vaginal tampon be used to empty the uterus and secure firm retraction. The bladder and rectum should be emptied, patient placed in Sims's position, douche given of two per cent. creolin through a Sims speculum, carry strips of iodoform gauze through the internal os, pack well, and finally fill the whole vagina with gauze. The gauze acted in three ways: It stimulated uterine contraction, favored dilatation, caused separation of the ovum by producing accumulation of blood between it and the uterus. If necessary divulse by the rapid method.

In placenta prævia Dr. Polak advised that the uterus be emptied when the first hemorrhage took place. He would tampon with iodoformized gauze, remove the gauze in about eight hours, and douche with an antiseptic. If the cervix would then admit one or two fingers, and it usually would, he would turn by the Braxton-Hicks method, and bring down a foot to act as a tampon.

Digital dilatation, podalic version and extraction had proven very successful in the hands of many, notably Grandin.

In accidental hemorrhage from partial separation of a normally placed placenta, rapid dilatation manually was indicated, or if the portio-vaginalis were effaced, the bloody method: rupture the membranes and deliver rapidly by forceps or version; remove the placenta immediately and tampon the uterus with iodoform gauze to control hemorrhage. The author thought that ergot given before delivery in these cases caused spasmodic action and tendency to stricture at the lower segment.

In post-partum hemorrhage from uterine atonicity give proper attention to the third stage of labor; if no hemorrhage, wait fully half an hour before delivery, grasp the uterus and keep up friction until there was firm contraction; if bleeding, express the placenta, afterward squeeze out clots and press the fundus well into the pelvic cavity; use ergot hypodermatically. He had so used it three hundred and twenty-one times without abscess forming, injecting into the deep muscular tissue on the posterior aspect of the thigh. Tampon the uterus. In tears control hemorrhage by ligature or suture.

In acute anæmia subcutaneous injections of salt solution had been particularly valuable. He had had a case of full bladder as a cause of hemorrhage, which had impressed upon him the importance of Dr. Waldo's advice always to empty this viscus.

In secondary hemorrhage (occurring after a day pe haps) empty the uterus with the finger, use hot douch ergot, tampon with iodoformized gauze.

Discussion upon this and other papers took place late

A Comparison Between the Mexican and Europea Pelvis, with Practical Consequences Arising from th Peculiar Conformation of the Mexican Pelvis.—PR FESSOR MANUEL GUTIERREZ, of the City of Mexico, re a paper in Spanish upon this subject. The Mexican pel was characterized by a general reduction in its diameters, which was the more remarkable as it approached the perineal floor, being made so by the great elevation of the pubic symphysis; by the great inclination of the excavation and of the straits; by the great extension of the perineum, and by the straightness and direction of the vulva. The consequences of this configuration were: 1, Some difficulties in extatic accommodation; 2, the peculiar manner of practising vaginal touch; 3, a certain tendency to facial presentation from the mechanism of delivery; 4, delivery sometimes slow and made painful by the difficult movement of descent, rotation, and extension of the head and by the accidents caused by the remaining of the ovoid in the vaginal canal; 5, these difficulties were sometimes manageable, but they often required the interference of art; 6, the conformation and diminution of the floor and pelvic outlet exposed the perineum to great danger.

A Study of Placenta Prævia, especially the Causes of the Hemorrhages.—Dr. Sarah Hackett Stevenson, of Chicago, read the paper. During the past ten years she had been teaching students a theory of the causation of hemorrhages in placenta prævia, which, with one exception, had not yet found its way into journals or text-books. The peculiar tendency to hemorrhages in placenta prævia was due to gravity and the mechanism of circulation of the parts. Gravity tended constantly to overcome the supports which held up the uterus and its contents and to drive them through the opening below. As to the circulation, the uterine artery entered the organ below, and pursued a tortuous course upward, but was straighter in the lower segment. The course of the veins was more direct and longitudinal than that of the arteries. When the placenta was implanted high, the general course of the arteries transversely to the uterus was opposed to gravity as a cause of hemorrhage; but when the placental implantation was low, as in placenta prævia, a rupture of a vessel was almost like opening the aorta. When the force of gravity became greater than that of the utero-placental connection, rupture of distended vessels took place with more or less profuse bleeding. Moreover, it was the author's opinion, based on a study of the direction of the vessels, that when uterine contractions took place, the blood was squeezed into the veins of the lower segment, which were already unduly distended in placenta prævia. The veins below become diverticuli for the blood pushed out of those above. Other factors might exist, but were not constant.

Dr. Zórraga, of Mexico, asked the opinion of those present upon the state of the circulation in the newly-born during asphyxia. In America and Europe it seemed to be the belief that the circulation and number of heart-beats were diminished. In Mexico observation had been that the opposite was the case, the heart failing only toward the end.

Dr. Stevenson supposed, if it were shown the heart-beat was accelerated, it would be of value in prophylaxis, as pointing to impending asphyxia.

Dr. Polak was asked whether he had seen iodoform poisoning from the introduction of iodoform into the uterus; and he replied that he had not. The agent, it seemed, came only in contact with the surface, and acted as a disinfectant, but was not absorbed.

Dr. Gutierrer said that in Mexico they were very much opposed to making cervical incisions in order to effect delivery quickly.

Dr. P. A. Harris, of New Jersey, said he had avoided making cervical incisions in one case by long waiting, and he knew of a surgeon being called to a case who preferred and actually performed Cæsarian section rather than incise the cervix, although he was acquainted with the work of others in delivering by the bloody method. He asked Dr. Polak whether actual danger had arisen in any case from hemorrhage.

Dr. Polak knew only of Dr. Marx's case, and in that instance the bleeding was controlled by ligature. By this means and uterine and vaginal tampon the danger was almost *nil*. Repiying to Dr. Stevenson, he thought there might be some danger in cases of placenta prævia. Danger of tear through the utero vaginal segment had caused some to stand aloof from the procedure.

Dr. Gutierrer said after-results were feared in Mexico.

Dr. Dewees, of Kansas, preferred to bring about cervical dilatation by use of chloroform or the lancet. He had used one or both of these measures successfully in about a dozen cases, seen in consultation, all simpler measures having been tried prior to his arrival. The lancet was used only in plethoric women, chloroform in anæmic. Replying to Dr. Polak, he said the supposed danger of increase of after-hemorrhage, when chloroform was used, applied, he believed, more to plethoric patients. He withdrew twenty to fifty ounces of blood, and dilatation followed almost immediately. Hot douches succeeded in one case.

Dr. Mitchell said he had been accustomed to tell students that chloroform favored after-hemorrhage, but was beginning to think it a mistake.

Dr. Knox, of Pennsylvania, had found tartar emetic hastened dilatation and delivery.

A Study of the Blood in Pregnancy.—Dr. Fernando Zórraga, City of Mexico, read a paper in Spanish on the above subject.

The Application of Graphies to the Fœtal Heart-Sounds.—Dr. Hugh Hamilton, of Harrisburg, Pa., read the paper, which had to do with the application of electricity to magnify and record the fœtal heart-bruits. The instrument presented in this connection was designed to raise one of the certain diagnostic signs of pregnancy out of the domain of sense into that of record, so that the tracings might be distinguished from those of maternal origin. The instrument was of Dr. Hamilton's own make, called a cardiophone. A technical description was given, and was followed by the statement that the slightest movement of the tympanum of the cardiophone would cause the telephone-receiver to vibrate with magnified vigor, so that it could be heard ten or twelve feet, and the nerve of a frog's leg, if it were connected with this, to contract and record its markings on blackened paper. Placing one cardiophone on the aorta of the mother and another upon her abdomen, connected in two circuits, they were brought to record their marks upon the same cylinder, so that the parallel tracings could be compared. The pulsations of the fœtal heart being 140 to 160, and those of the mother 75 to 80, made the difference in the tracings or cardiographs.

In very fat individuals or certain positions of the child in utero it was impossible to hear these sounds or to get perfect records. Should the several souffles give symmetrical markings, it would be conclusive evidence of their being maternal. The apparatus occupied a box three by three by six inches and weighed a quarter of a pound.

Second Day, Wednesday, September 6th—Morning Session.

The Status of Obstetrics in General Practice.—Dr. Eliza H. Root, of Chicago, read a paper with this title. The question was asked, Why is the physiological and perfectly natural function of child-bearing so frequently followed by health-ruining results? The answer was given, after naming the conditions which drove the patient to the gynecologist, which were traumatic or inflammatory. The second were due largely to septic infection at or during the lying-in period. Careless practice or ignorance on the part of accoucheur or patient were the causes. The physician, she regretted to say, often assumed the responsibility of caring for labor cases without sufficient clinical experience obtained during student life. The necessity for better opportunity to obtain such experience in medical schools was pointed out. The fault often lay with the patient, who might call the physician only after the occurrence of eclampsia. She permitted constipation to continue, causing toxæmia and mechanical interference. One of the most important demands was proper after care, and the physician should not permit any degree of poverty on the part of the patient to cause him to make but one visit. Visiting physicians by districts among the poor in cities was approved. Cleanliness was still much neglected. More attention should be given to the sick-rate, less to the death-rate; for the former being looked after, the latter would care for itself.

The Induction of Premature Labor.—Dr. J. H. W. Chestnut, of Philadelphia, read this paper. Cases calling for the induction of premature labor included: 1, Cases of contracted pelvis which would render labor at term dangerously difficult to the mother or child. 2, Cases of maternal disease which progressively endangers the life of the mother. 3. Cases in which in previous pregnancies the child has died in the latter weeks of gestation. 4. Cases of hopeless disease of the mother, for

the sake of the child (which seldom occurred). 5. Cases in which the child is known to be dead. 6. Ovarian, bony, or malignant tumors, or atresiæ of the canal.

Contracted pelvis, especially in Americans, was uncommon. In a considerable practice the author had seen but one case in which the conjugate diameter at the brim was less than two inches and a half. But he had seen many cases where it was only three to three and three-fourths inches. If it were two and three fourths inches to three and one-fourth inches, he would advise the induction of premature labor in preference to waiting until term and resorting to symphyseotomy or other operative procedure. Cæsarean section, notwithstanding its recent improvement, was still a formidable operation, fraught with danger to both parties. The same objection applied to its modifications. Symphyseotomy was open to the objection that it was frequently followed by hemorrhage and the pelvic strength was impaired.

He would also induce labor in justo minor pelvis where the antero posterior diameter at the brim was under three and one-half. The difficulty of diagnosis in time was a great obstacle, patients often calling the obstetrician late. One should in all instances, if possible, obtain the patient's previous history and take the external, and, if possible, at least one internal measurement of the pelvis—from lower edge of symphysis to promontory of the sacrum. In the hands of the general practitioner, especially, was induction of premature labor the safer operation.

Dr. Sarah Stevenson, of Chicago, and Dr. Upshur, of Richmond, heartily endorsed the spirit of the paper of Dr. Root.

Dr. Gutierrez said they had tried regulation of midwifery by examination in Mexico, but the first attempt failed. A law was now contemplated requiring courses of three and five years.

Dr. Hugh Hamilton, of Pittsburg, offered the following resolution: That this section hereby protests against the practice of obstetrics by foreign or domestic midwives, without proper regulations.

The resolution was referred to a committee to report Thursday.

The President appointed the following on the committee: Drs. Root, King, Upshur, Gutierrez, Stevenson, Zorraga, Chestnut, Castellanos, and Hamilton.

Aids to Easy Parturition.—Dr. A. J. C. Saunier, of Chicago, read the paper. The points which he should mention might be minor in themselves, but taken collectively they were likely to make a great difference in the ease of parturition. The first aids should be instituted early in life. The mother should be warned of habits likely to endanger the general health of her daughter, teach her to avoid habitual retention of urine, constipation, dresses dragging upon the waist. During menstruation, prevent undue congestion and secure freedom of flow. After pregnancy, diet was important, the author advising the use of such food as did not favor undue osseous development, corn bread, wheat, other cereals, and food which contained much earthy salts, giving white bread, potatoes, vegetables, acid fruits. The latter (acid fruits) kept the bowels free and caused solution of the earthy salts in other articles, so that they could be carried off by the kidneys—proof of which he had seen in the softer and more cartilaginous bones of the child.

Pelvic troubles, especially inflammations, should be corrected. Cultivate occasional vaginal douche and bathing. During the last week apply hot cloths on perineum, at least 118° F., a hot douche, etc. Abridge the first stage by securing frequent and firm uterine contraction by massage of the abdomen and digital assistance at dilatation, keeping the finger in perhaps half an hour, and thus avoiding the necessity for frequent re-introduction. The best time to perform cephalic version was about two weeks before labor, assisted by the genu-pectoral position.

Dr. Chestnut, of Philadelphia, doubted the propriety of excluding food which would favor bone development in the child, limiting the mother's diet to white bread, potatoes, fruit, etc., even if this course would leave a softened condition of the bones of the child. It might leave the child in an unhealthy state which it would be difficult to repair. He also feared the use of cocaine or other agents benumbing the parturient tract.

Dr. Saunier said in reply, that he had recommended this diet to mothers for twelve years and had not observed osteomalacia in the children or other evil result. Replying to an interrogatory by Dr. Upshur, he said he had seen no toxic effect from the use of cocaine in the genital tract. He usually introduced a suppository containing ten grains of cocaine. Nor had he observed that there was greater frequency of tears.

Dr. Upshur had observed toothache or loss of teeth in women deprived of phosphates, etc., relief from toothache being obtained by administering hypophosphites, etc.

Dr. Saunier had observed no ill effects on the teeth, etc., from the restricted diet.

Afternoon Session.

The Mechanism of Labor.—Dr. Jacob Charles Rutherford, of Providence, R. I., in presenting this paper, quoted freely from others which he had published bearing on the same subject. He held that the theory of the mechanism of labor, as advanced by ancient and many modern writers, was erroneous. That the parturient canal was not curved, as had been claimed, could be shown, he said, by a study of the anatomy of the parts, the changes which took place during pregnancy, and the phenomena of labor. The parturient canal, he held, was angular, not curved; when the presenting part had reached the bottom of the trough in the pelvic floor rotation was complete; flexion and extension took place at the utero-vaginal angle. Stress was laid upon the utero-vaginal angle in a study of the axes of the parturient tract. In high forceps delivery, traction should be made in the line of the uterine axis; in low forceps delivery, in the line of the vaginal axis.

Obstetrics among the Negroes of South Carolina.—Dr. P. Gordon de Saussure, of Charleston, read the paper. It was based principally upon statistics of private practice and of the health board of Charleston. It was difficult to obtain exact figures as to age, commencement of menstruation, etc., from negroes. Everything with them was "about," and a year or a few years was regarded as of little importance by them. In thirty-three cases where the date and age were known exactly, menstruation began on the average at 13.1 years. In forty-eight cases the average age at which the menopause arrived was 48.8. He had delivered some who were said to be aged fifty-three.

Amenorrhœa, dysmenorrhœa, and hemorrhage were extremely rare. They were more fruitful than the whites, averaging 6.8 children; but since their condition had changed and they were compelled to provide for themselves, they tried to shirk the responsibility of motherhood and very frequently produced abortion by drugs—never mechanically. Pregnancy ran a natural course, no disturbance, except that eclampsia was not uncommon as compared with the whites. Perhaps it was due to anæmia from poverty. He knew of only three cases of extra-uterine pregnancy. Septicæmia or puerperal fever was extremely rare, in spite of frequency of abortions and filth. At least nine-tenths of the labors were attended only by negro midwives, who practically did nothing. They never introduced the finger. If the placenta did not come away the midwife tied the cord to the mother's ankle with the view of preventing it from slipping back, and gave her a bottle to blow in. The latter custom proved useful, in causing the diaphragm to descend and aiding expulsion. Syphilis existed in at least seventy per cent. of them. The pelvic measurements were more ample than those given for whites, and delivery was very easy. The dirt and filth in which they lived was almost beyond imagination, and the freedom from puerperal sepsis could be accounted for only on the theory that this condition arose, not from auto-infection, but from intro-

duction of poison from without. As said, midwives never made vaginal examinations nor undertook mechanical delivery, nor induced abortion with instruments.

The Therapeutic Application of Chloroform in Labor.—Dr. J. N. Upshur, of Richmond, opened his paper with the statement that a long experience with chloroform had led him to question its supposed safety in labor. We were apt to forget that labor is a natural phenomenon, except under unusual circumstances. Chloroform when used in such cases might, he thought, cause some form of dystocia and call for interference. A full appreciation of the possible dangers attending or following the use of the agent required reference to its action under ordinary conditions in the production of the different degrees of anæsthesia. There was its influence upon the cardiac nerve centres, upon the cerebral and spinal centres, upon the respiration, etc. Possible dangers were weakened heart action, interfering with convalescence, vascular relaxation, diminished muscular excitability and atonicity during parturition, incomplete retraction of the uterus, subinvolution, spongy condition of the womb, rendering sepsis more liable, interference with oxidation before delivery, thus endangering the life of the child. Although few cases of death had been reported from chloroform in obstetrics, yet it was a question whether some of those reported within twenty-four hours as due to heart clot, etc., were not the result of chloroform. He would not, therefore, administer chloroform unless it were imperatively demanded. If it were employed, he suggested that it might be beneficial to give atropine, strychnine, or some agent which would, in some measure, counteract its influence.

SECTION ON HYGIENE, CLIMATOLOGY, AND DEMOGRAPHY.

Albert L. Gihon, M.D., Medical Director U. S. N., Washington, President, in the Chair; English Secretary, Peter H. Bryce, M.D., Toronto, Can.; Spanish Secretary, Pedro José Salicrup, M.D., New York City.

First Day, Tuesday, September 5th.

This section met conjointly with the Section on Marine Hygiene and Quarantine, at Grand Army Hall. The delegates assembled at 3 P.M., and at 3.15 the meeting was opened, when, on motion, Dr. A. N. Bell, of Brooklyn, took the chair, and then, in due form, vacated it in favor of Dr. A. L. Gihon, Medical Director of the United States Navy, the President of the Section on Hygiene.

Surgeon-General Wyman, Marine Hospital Service, was detained by duty.

The papers listed for the afternoon's meeting were as follows:

1. The opening address, "On Sanitary Motes and Beams," by Medical Director Albert L. Gihon, United States Navy, President of the Section.

2. Normal address on "National Quarantine," by Supervising Surgeon General Walter Wyman, United States Marine Hospital Service, President of the Section on Marine Hygiene and Quarantine.

3. Address in Spanish on "The Sanitary Organization of the Spanish Army," by Dr. Felix Estrada y Catroyra, of Havana, Cuba.

4. Address on "The Proper Status of the Medical Profession in the Government of Nations," by Professor Cornelius G. Comegys, M.D, of Cincinnati, O.

Dr. Gihon prefaced his paper by the text, "And why beholdest thou the mote that is in thy brother's eye, but considerest not the beam that is in thine own eye?" (St. Luke vi. 41, 42.)

These words of the Teacher of Humanity, which the beloved physician of the first century has recorded, are an appropriate text for the opening address in the important section with whose conduct I have been charged in this Congress.

Time was, and that no long time, when Hygeia, the neglected Cinderella of the medical family, shrunk unnoticed among menials: now that she graces the *salon*, her proud sisters caress her and suitors court her favor. As an old admirer of this fair mistress, whose colors I have worn through youth and manhood, I may be pardoned the personal exaltation that I have lived to see her suzeraine.

The ascendency of hygiene has broadened and glorified medicine without dimming the lustre of any other branch; but though her cult is established, her mission has not ended with the recognition of her supremacy and the faithful following of her own ilk. To day she turns to the people and their rulers, outside the medical fold, and demands the place in their councils that is hers of right. A makeshift share in the administration of the sanitary interests of the country has been grudgingly allowed, but the inexorable demand of modern enlightenment cannot be satisfied until the conservator of the public health shall sit a peer among the rulers. The Minister of War may build mighty engines of destruction and defence, and muster vast armies and navies, which disease can disperse with a weapon so tiny that the eye cannot discover and no military expedient antagonize. The Minister of Finance may fill his treasure houses with gold and silver by the ton, which can buy human souls, honor, virtue, independence, everything but the boon of health, God's free gift to men, through which alone he can be like His own glorious image. Commerce, agriculture, manufactures, fishery, mining, and all the industrial occupations of the human race, which are now the objects of the intelligent supervision of cabinet ministers who are grandmasters of political economy and social science, cannot thrive without the vigor of human blood and brains and brawn, which are the machinery of these occupations; yet until this decade it has not been thought that the intelligent supervision of a grand-master of the divine science of medicine was necessary to preserve this vigorous health of the community, without which even these other ministers can themselves only imperfectly perform their own offices of administration.

When I entered the service of the Government of the United States, as an officer in the Medical Department of the Navy, nearly forty years ago, with a minimum of experience and a maximum of enthusiasm, and an exalted opinion of the dignity and responsibility of my charge, which a lifetime has only intensified, I was astonished at the total ignorement of sanitary provision then prevailing in the naval service. Medical officers were curtly reminded that their opinions and advice would be asked when desired; their protests at acts that filled the hospitals and mortuary lists were contemptuously unheeded; they were reproved for officiousness and punished as insubordinate; disabled sailors and marines were discharged, and their places and those of the dead were filled without regret or remorse, but with the shameless boast, "If men die, we can ship others," like the Netherlands commodore, some of whose crew had been killed by the careless firing of a shotted saluting gun, who accepted the apology for the accident with the nonchalant remark, "Dere are plenty more Dutchmen in Holland."

The battleships and cruisers of modern navies are not more like the brigs and sloops-of-war of forty years ago than are the cleanly, well-fed, comfortably clad, and cared-for enlisted men, who go ashore daily, subscribe for newspapers, and write letters, a different race from the begrimed and degraded "shell-backs," who were ordered to their work with curses and punished with brutality for offences which neglect and ill-treatment had incited. The naval and military establishments have considered the beam in their own eyes, but civil authorities are still purblind to the necessity for organized intelligent sanitary supervision and direction, and grope for success only under the flash light of a pestilential visitation.

The following is from a recent editorial, "Whether Cholera has or has not Made its Appearance at Chester," which is practically one of the suburbs of Philadel-

phia: "It is certain that the conditions reported to exist there are in the highest degree favorable for the introduction and spread of that disease. All accounts represent the neighborhood in which the alleged cases occurred as filthy beyond description, and occupied by a class of persons who pay no attention whatever to the laws of health or personal cleanliness. Of course, the country now has the pleasant assurance that the place is to be thoroughly cleaned and effectively quarantined, but why were not these steps, necessary for the protection of the public health, taken before the resulting disease, whether cholera or not, had gained such a footing that already five persons have died from it. The time to lock the stable-door is before the horses housed therein are stolen, and the way to treat contagious diseases is to prevent their appearance, and not wait for them to gain a foothold and then try to stamp them out."

The Secretary General has announced that the proceedings of this section and its congener, the Section on Marine Hygiene and Quarantine, will constitute a special feature of this Congress. It is therefore incumbent upon us before adjourning to declare very positively the opinion of the members of this section—experienced practical sanitarians from every country of the western hemisphere—that the interests of the public health must be entrusted to a department of the government especially charged with their administration, with equal independent executive authority as given to other national departments. Temporizing legislation under the spur of emergencies does not befit this age. As the enlightened physician seeks to prevent his charges becoming ill, so should the guardian of the public health be able to forestall these emergencies, whose pecuniary cost in money expended and wasted, in trade paralyzed and diverted, in labor and wages lost by the sick and terrified and dead, in a single epidemic, exceeds that of maintaining an efficient sanitary service for the whole country for a year.

SECTION ON MARINE HYGIENE AND QUARANTINE.

WALTER WYMAN, M.D., SURGEON-GENERAL MARINE HOSPITAL SERVICE, WASHINGTON, PRESIDENT.

OWING to the absence of Dr. Wyman, on duty, Dr. Gihon presided over the two sections, and as one. They met in the Grand Army Hall, on Tuesday afternoon, September 5th, at 3 P.M.

DR. A. N. BELL, of Brooklyn, took the chair while the president of the section delivered his address.

DR. GIHON'S timely address was well received.

DR. HIBBARD, President of the American Medical Association, followed, supplementing Dr. Gihon's lengthy address. Speaking generally, he said that it was the first consideration and first duty of every government in the world to make its people happy. The first and strongest element is good health, a sound mind, and an upright conscience.

Everything in this world is under the dominion of law. Everything is under the influence of law. It is all God's law. If true to its mission, science's function is to investigate the operations of such laws. Science must interpret them for the benefit of mankind. Many of the laws we cannot change, but we may direct them in one way or the other for the betterment or detriment of mankind. Every step in advance gives us, scientists and sanitarians, new vantage ground from which to make a new attack or charge on behalf of our mission. By extending the benefits of science we shall make the people happy.

Let the Government take every means to advance the study of natural laws. They are susceptible of a good and an evil interpretation. In a "government by the people and for the people" we, as scientists and sanitarians, must have the people with us. We must continue to work on patiently year by year until we reach success. Let human agency give direction. We cannot reach perfection at once. It will take time to bring into subjection all the diseases that invade our land and destroy our people.

DR. FORMENTO, of New Orleans, president of the board of health of Louisiana, addressed the sections on the matters before them, of marine hygiene and quarantine. He was opposed to any central control, such as would be applied in a national board of health. Louisiana was ably qualified to and had protected herself for years past. In short, he was in favor of every State being its own protector. He individually feared interference with State sovereignty. He also feared, that if a central or national board of health was created, politics would exercise a baneful effect. In naming a minister of public health such influences might obtain.

Returning to Louisiana, he said that she had the best quarantine service in the world.

DR. SCALES, of Mobile, president of the board of health for the State of Alabama, referred to some twenty years' connection with quarantine work. Once he also had been a States' rights' man; he had ceased to be (applause); he was in favor of a national system for the protection of all, allowing individual States to do their utmost to keep out pestilence and disease of all kinds.

There was a general and interesting discussion, as over fifty sanitarians and experts in public health and quarantine were present.

DR. DAVIS referred to the excellent work of Surgeon-General Wyman in keeping out disease.

DR. GRANT BEY, of Cairo, Egypt, said that Great Britain was feeling her way for a public officer of health. In Great Britain the local government boards assisted the general government by collecting information of enormous value in such work. He spoke at length, and said in conclusion that if America succeeded in creating a department of public health, with a minister of public health, she will take the first place in sanitary science.

DR. RAUCH, of Illinois, said that his people were in favor of protection such as would be afforded by a national board of health, or its working equivalent, be its name what it may.

DR. LEE, State board of health of Pennsylvania, said that it was a broad question. Local quarantines, local prejudices, and local interests will have more or less force. He believed in an efficient national bureau. Shall it be a national board of health or a department?

DR. SCALES, of Mobile, president board of health, State of Alabama, was in favor of a national bureau of health. He was heartily in favor of yielding the States' rights' point. We want the maximum of protection.

DR. SHAKESPEARE, of Philadelphia, said that the question must be looked at from a general standpoint. It was too broad, too important to be sectional—a national board of health. No State should be allowed to do anything detrimental to the welfare of the body politic. Sanitary science and public health should be placed on the same level as any of the departments of the State.

DR. ATKINSON endorsed previous speakers, and said that a department of State medicine should exist in every nation.

DR. HOPKINS, of Georgia, recognized the necessity for a national board of health.

DR. FLICK, of Philadelphia, said that it was the largest subject that any body of men had ever attempted to discuss. Disease no longer was regarded as a visitation of Providence. We must create laws before we can enforce them. Laws to meet the indications must be created by certain bodies—national, State, city, and borough. Ask the Government of the United States to create a department of public health. Every State should have its department of sanitary science in the same manner that every State has its judiciary. Time, and time alone, can elaborate such a perfect and far-reaching system.

DR. O'DANIEL, of Georgia, said that Georgia had no State board of health. He referred to the recent ap-

pearance of yellow fever in his State. The national Government had to meet the emergency.

Dr. Mulligan, of Oregon, favored a national board of health, under Government control, a charge for the benefit of all. In an enterprise so vast the beginning will be small, but the growth will be steady, the whole of the greatest value to the country and people.

Dr. E. S. Kelly, of Minneapolis, Minn., was heartily in favor of any resolution by which an end so desirable could be brought about. He said that the Northwest depended upon Grosse Isle, in the Gulf of St. Lawrence, Canada, and New York to protect her.

Dr. Lawlor, of Massachusetts, approved any measure of the nature of that suggested. There should be a national standard. States should be compelled to live up to it. An effectual barrier should be placed between us and cholera, small-pox, yellow fever, as well as any and all diseases that may reach our borders.

Dr. A. N. Bell, of Brooklyn, likewise was heartily in favor of such a measure, but feared that local influences might interfere.

Medical Director Albert L. Gihon said that Mexico had a supreme council of health, presided over by Dr. Eduardo Liceaga, present with us. That the United States wanted just what Mexico already had. For a long time the profession had not occupied the position due it. He remarked that we submit to be minified. Medical men should urge these matters for the benefit of the public, and never cease their efforts until the end was attained. A national department of medicine was wanted, composed of medical men, versed in matters of public health and allied themes.

As the result of much discussion, the following resolution was unanimously accepted:

Resolved, That in the opinion of the section on hygiene, climatology, and demography of the Pan American Medical Congress, the interests of public health, in every country, should be and must be entrusted to a department of the Government especially charged with their administration, and that while the precise form of administration may be left to legislation, the indispensable requisites are that it shall be national, that it shall have parity of voice and influence in the national councils, that it shall have independent executive authority, under the limitations common to other departments, and that it shall be entrusted to educated and experienced medical men who alone are competent to assume its responsibilities.

Dr. Hopkins, of Georgia, made a motion, which was seconded and carried: That it is the duty of every State, not having such, to enact laws providing for a State board of health.

The section adjourned until the next day.

SECTION ON GENERAL SURGERY.

Third Day, Thursday, September 7th—Morning Session.

Causes contributing to Failure in the Treatment of Hip joint Disease.—This was a paper by Dr. A. M. Phelps, of New York City, and read by title only. The author then exhibited some apparatus for the treatment of hip-joint disease, support of the spine, and correction of club-foot.

The first exhibition was a corset made of aluminium. This corset was light, strong, and could be used while bathing. It is thin enough to allow a lady to wear an evening dress with it.

A cast of the body is first made, which is sent to the foundry, and an anvil is made and then polished. Over this anvil the sheets of aluminium are hammered to the desired shape, then polished and holes cut through it.

Club-foot Machine.—This is constructed of straps, slides, plates, and levers, and after being adjusted to the foot a pressure of about two thousand two hundred pounds could be applied in any direction required.

Hip-joint splint is so constructed as to give traction in the proper direction. Cases treated with it do not recover with an angular deformity.

Dr. Lee, of Pennsylvania, remarked that he had been trying to obtain an aluminium corset of sufficient strength to give the required support in cases of Pott's disease, but found all his specimens so soft and yielding that they proved to be useless. By the addition of copper and nickel he could obtain the required strength, but they were much heavier than pure aluminium.

In regard to the club-foot machine, can you use this great amount of pressure without risking the crushing of the soft tissues? Also, what is the comparative cost of the aluminium jacket?

Dr. Phelps replied that the jacket was pure aluminium. After about two years of experimentation they found that by heating the sheets up to a certain temperature, and then by working and hammering it well, it became as hard as iron. It cost from $25 to $30 to make one. It is not intended for the treatment of acute cases, but as a brace for cured cases.

The force applied to the club-foot machine should be regulated by the operator, and I have never seen any injury resulting from its use. It is unnecessary to use its entire force, but it is much better to have a machine of great force than one which may lack the required strength in some exceptional case.

Gunshot Wounds was the title of a paper read by Professor Marin, of Puebla, Mexico. A man was brought into the hospital suffering from a pistol shot wound, made by a ball of 44 calibre. The ball entered in front at the root of the neck, passing downward and backward, and out of the body. He was suffering from the effects of profuse hemorrhage; was pale and bloodless. When brought to the operating-room he was unconscious. I made a thorough exploratory examination, and made an incision to find the source of the hemorrhage. I found that in its passage the ball had made a fissure or rent in the wall of the brachio-cephalic vein. The coats of the vein were pinched up and sutured by means of a continuous suture, which arrested all hemorrhage. The next day the wounds of the muscles were sutured, and the man made a good recovery without any symptoms of thrombosis or septic infection.

The paper was discussed by Drs. H. O. Marcy, of Boston, Ernest Laplace, of Philadelphia, Pa., and Rudolph Matas, of New Orleans, La., who congratulated him, not only upon his successful operation, but more especially upon the principles of it, in restoring the circulation to its normal condition, leaving it as before the infliction of the injury.

The Mechanical Treatment of Osteo-arthritis of the Knee was the title of a paper by Henry Ling Taylor, M.D., of New York. Osteo-arthritis of the knee, or "white swelling," is usually a tubercular process, beginning in an adjacent epiphysis or in the synovial membrane, and, if unchecked, finally involves most of the joint structures. It is accompanied by the usual symptoms of chronic joint inflammation, of which spasm and atrophy of the muscles acting upon the joint are practically the most important, as indicating most exactly the degree of joint irritation, and also by certain characteristic deformities at the knee, namely, flexion, eversion, abduction (genu valgum), and subluxation backward of the head of the tibia. The deformities are due to the mechanical conditions under which the spasmodically irritated thigh muscles act.

General Treatment.—Improve the nutrition of the patient, and thus insure a blood-supply of good quality to the diseased area, facilitating the reparative process. One of the most gratifying results of proper mechanical treatment is the marked and speedy gain in general health and vigor.

Local Treatment.—Inaugurate and promote the process of repair at the site of disease, and to prevent or correct deformity, in order to restore, so far as possible, the functions of the joint. These local indications are met by mechanically providing conditions favoring the relaxation

of the spasmodically contracted muscles, a normal local circulation, gradual correction of the deformity, and, later, the protected use of the joint. In the stage of irritation and disintegration strict local rest is enforced by the use of an apparatus giving counter-extension and fixation, and for a month or two the patient is kept recumbent. When the local circulation and position of the limb has sufficiently improved, locomotion is permitted, first with, later without, crutches, but always protected by the apparatus. After this period of enforced rest, and the reparative process is completed, the neuro-muscular apparatus should be regulated and strengthened by allowing limited motion at the joint, and the joint gradually trained to bear weight preparatory to discarding all treatment.

Apparatus.—Any good supporting and protective apparatus, with a lock joint at the knee, such as the Dow apparatus, answers all ordinary purposes. It should afford absolute protection from external and internal trauma, with progressive replacement of distorted parts at all stages; first with enforced disuse, later with protected use, limited by the operator to meet all conditions present.

Improved Long-traction Hip-splint, with Proper Method of Applying Adhesive Plaster for Counter-extension.—This splint was demonstrated by Dr. Henry Ling Taylor, of New York. The splint consists in a hollow shank, firmly attached at its upper end to a side-plate, from which strong curved steel horns spring to carry the perineal strap. In the hollow shank plays a notched bar, which is worked by a key, bent under the foot at a right angle to give attachment to a strap which is buckled to two strips of diachylon plaster, each ending in a buckle just above the malleoli. The strips are one and one-half inch wide and long enough to reach from just below the level of the groin to two inches above the malleoli, on the outer and inner aspects of the limb, respectively. To each plaster are sewed two tails of three-quarters of an inch rubber plaster, above the knee and at the lower end. With both long strips in position, the narrow strips are to be evenly wound in a spiral direction upward around the limb, beginning with the upper pair. They should be held in place by a bandage or laced legging. Plasters applied in this manner pull from the thigh, so that the knee is protected, and give a firm basis for continued traction. The improvement in the apparatus described, over the original Taylor hip-splint, consists mainly in the substitution of the strong curved steel horns of peculiar shape for the horizontal hip-band formerly used. The change was made on account of the greater comfort and convenience of the new arrangement, but chiefly to give greater rigidity to the apparatus.

Improved Apparatus for Pott's Disease was a paper by Dr. H. L. Taylor, of New York, and read by title only, followed by an exhibition and demonstration of the apparatus.

It was devised by Dr. C. Fayette Taylor, and differs from that shown to the New York State Medical Society in 1863 in the following points: 1. The parallel vertical bars have been lengthened, and end in hooked pieces passing well over the shoulders near the neck. 2. The hinges differ somewhat in construction and are screwed to the bars, being retained solely for the purpose of facilitating the modification of the apparatus corresponding to the varying indications of the case. 3. The horizontal hip-band is discarded, and replaced by a rigid steel bar or vertical hip-band having the shape of an inverted U; to the upper part of this band the lower ends of the vertical bars are firmly attached. The ends of the ∩-shaped band are fitted into the post-trochanteric sulcus on either side, and together with the hooked pieces at the root of the neck fix the apparatus laterally, besides assisting in antero-posterior and vertical fixation. The lower ends, being points of contact with the skin, are protected by hard-rubber plates. 4. Hard-rubber pads are used, instead of the soft pads formerly employed, to transmit the leverage of the apparatus to the region of the spine which it is desired to protect. 5. Instead of the straps encircling the arm, formerly used to get a fixed point for counter-force in front, a "chest-piece" is employed, consisting of two ear-shaped or triangular hard-rubber pads, fitted under the clavicles and resting on the pectoral muscles, and joined by a stiff steel bar, curved forward to escape the chest, and so contrived that the distance between the plates may be increased or diminished at will. The chest-piece being in position, is buckled to straps coming from the ends of the shoulder-hooks above, and below it is strapped to a buckle at the angle of the ∩-hip-band on either side, thus leaving the arm free and the axilla untouched. 6. The apron which holds the whole apparatus forward reaches to the posterior border of the axilla on either side, and from the trochanter to the arm laterally, and is secured by straps and buckles to the apparatus. 7. Perineal straps pass from the lower border of the apron in front, under the thighs, to the ends of the vertical hip-band.

It is to be understood that appropriate modifications of the form of the apparatus are made to correspond with the indications presented by disease in the different regions of the spine, and by the character and amount of the deformity. Most cases above the eighth dorsal will require, in addition, Dr. Taylor's circular pivoted head-support or chin-rest, which is easily fitted to this apparatus.

Apparatus for the Correction of Talipes Equino-varus and for the Retention of the Corrected Foot.—This apparatus was exhibited by Dr. H. L. Taylor, of New York. The essential points in the method of its use are: 1. The preservation of the heel cord as an aid in unfolding the foot. 2. The gradual reduction of the varus deformity first, afterward of the equinus. 3. Exact prehension of the foot by means of an apparatus not attached to the shoe, and by adhesive plaster applied to the leg. 4. The application of leverage to the inner side of the foot and leg. 5. Thorough mechanical after-treatment.

Gastrostomy for Relief of Œsophageal Stricture was the title of a paper read by Dr. Ernest Laplace, of Philadelphia, Pa. My case was that of a man who had been healthy all his life, who gradually developed a difficulty in swallowing, until finally he was unable to swallow even water. The smallest-sized tube could not be passed by the stricture. We performed gastrostomy. We first sutured the stomach to the abdominal wall, and, on the third day after, punctured the stomach wall with a thermo-cautery and fed the patient with peptonized milk. After a few days the patient was allowed to chew his food before it was placed in the stomach. In a short time, to our surprise, he was able to swallow his food without difficulty. The patient was anæsthetized for the purpose of closing the gastric fistula. Upon making an examination of the interior of the stomach with one finger, as far as we could reach, we found a pediculated mass, which evidently was at first a polyp which afterward had become pediculated. The stomach was closed without the removal of the growth, which may in time be digested. Since the operation the patient has experienced no further trouble from the growth.

A second case of stricture which I operated upon, dilating the œsophageal opening, also made a good recovery and has gained twenty-five pounds since the operation.

Dr. Heuff, of San Antonio, in discussing, said, I performed such an operation on a girl, in 1878, who made a good recovery and is alive to-day. At first the food was fed without allowing the patient to chew it. The result was a steady loss of flesh; but as soon as she was allowed to chew her food the mixture of the saliva seems to have had a marked effect upon her general health, and improvement thereafter was uninterrupted.

The paper was further discussed by Dr. Ernest Laplace, of Philadelphia, Pa.

Orthopedic Treatment of Infantile Paralysis was the title of a paper read by Dr. L. A. Weigel, of Rochester, N. Y. In this paper he laid special stress upon the fact that the prevention of resulting deformity is much easier

than the subsequent management of the same. The importance of artificial supports are not fully appreciated by the general practitioner, who should not depend upon drugs, but should adopt some form of support at once which will keep the limb in its normal position.

Gymnastic Apparatus for Scoliosis.—This paper was read by title only, by Dr. L. A. Weigel, of Rochester, N. Y., who then proceeded with a demonstration of the apparatus, together with a paper jacket made of alternate layers of paper strips and linen.

Transplantation of the Conjunctival Membrane from the Eye of the Rabbit to the Human Subject was the title of a paper by Professor J. R. Wolfe, of Glasgow, Scotland, who gave a demonstration of his method as follows: My instruments consist of a common dressing-forceps, spatula, and blunt-pointed scissors. The rabbit is chloroformed, then with a straight needle I pass a fine silk ligature between the conjunctiva and the membrane of nectitens, at different points, which serves the purpose of marking out the piece to be dissected off as well as lifting it up. The ligatures are slightly stretched and the piece dissected off. This piece is then spread upon the dorsal surface of the hand, where it will dry and remain perfectly flat. By the time the field upon which it is to be transplanted is prepared, the dissected piece of conjunctiva will be as stiff as parchment. It is lifted off the hand with the spatula and placed upon the prepared field, where it will adhere without any curling up or other difficulties, and a few requisite sutures complete the operation.

Transplantation of Skin Grafts to the Eyelid was the title of a paper also by Dr. Wolfe, of Glasgow. I first stitch both eyelids together; then dissect up the outer portion of the upper, or both lids, as the case may require, getting a clean raw surface upon which to place the grafts After obtaining my grafts from the arm or elsewhere, I wash them in warm water, and spreading them upon my finger carefully remove all adhering substances. They are then placed upon the prepared lids, without sutures, and a simple dressing of lint dipped in warm water applied. In taking measurements for the graft required I always carefully allow for shrinkage.

The Technique of the Plaster-jacket was read by title only, by Dr. Reginald H. Sayre, of New York City, who then, with the aid of a young female patient, proceeded to give an actual demonstration of making and applying the jacket upon the patient while partially suspended by the head and arms. He used corn-plaster felt for padding, to avoid too much pressure. In young, growing females breast-pads should be used, so as to give the mammæ an opportunity to grow. Place pads over all bony prominences. With the patient partially suspended, the operator nips the child between his knees to steady her and proceeds with the application of the moistened bandages. Bandages should be washed before the plaster is applied to them, and then hand rolled. Begin at the waist first, and the meshes should be rubbed very closely together while being applied. Make the jacket longer than necessary, and trim it down afterward. Make it thicker at the waist. Run the strips up and down in a zigzag manner. Slit the jacket with a common pruning-knife. When thoroughly dried, put it on the child, trim out the armpits and flexors of the thighs.

A Bandage for Protecting Skin Grafts after being Applied to Wounds was the title of a paper by Dr. Oscar J. Mayer, of San Francisco, Cal., accompanied by a demonstration showing how the after-treatment was simplified; the results obtained were claimed to be more satisfactory, and the period of healing considerably shortened.

In what Class of Cases is Drainage Required? Read by Dr. H. O. Marcy, of Boston, Mass. In all wounds we must take into consideration the condition and various resisting powers of the individual patient, together with the character of the injuries and ensuing complications.

In almost every operation, if the operator is as careful as he should be in sterilizing all materials, including the hands of himself and his assistants, and carefully close the wounds, there will be use for neither drainage nor antiseptics. All healthy tissues have a certain amount of resisting power to protect themselves from infection. All aseptic wounds should be carefully closed and covered with iodoform collodion. Drainage in aseptic wounds is unnecessary and dangerous, and without drainage, clumsy antiseptic dressings in aseptic wounds are avoided. Better knowledge of wounds will restrict drainage to those of a septic character alone.

In the discussion which followed Dr. Quimby agreed with the author that drainage tubes were foreign bodies, and, unless carefully watched, were a source of danger.

Dr. McRae, of Georgia, claimed his experience in the use of iodoform collodion in wounds over bony prominences was, that although he used soft padding underneath, the contraction due to the collodion had produced pressure necrosis, and he therefore was not in favor of its use.

Dr. Prewt, of St. Louis, claimed that the fluids of the body were not septic, but where one expected a large amount of exudation he had better use drainage; otherwise, not.

Dr. McCosh, of New York City, did not approve of indiscriminate drainage, but thought it unwise to sew up a wound too tightly and cover it with an impervious dressing, especially where all bleeding had not stopped. It is better to leave a little space between the sutures, or else slip in a few strands of silkworm-gut and allow the fluid to ooze out. If in the abdominal cavity, I flush it with hot water, but unless some indication calls for it, I insert no drainage-tube.

Dr. Laplace agreed with Dr. Marcy in every particular.

Dr. Oscar J. Mayer, of San Francisco, differed with Dr. Marcy in many essential points.

Dr. Jacob Frank, of Chicago, claimed, in his hospital experience that he could not get more than fifty per cent. of the wounds to heal without some suppuration, be it never so slight, and this, too, notwithstanding all careful sterilization before and during the operation, and believed many cases might be classed as auto-infected.

Before operating, the surgeon should have a thorough knowledge of the condition of every organ in the patient's body, and then use his own judgment as to drainage. He was at a loss to understand what harm a thoroughly sterilized drainage-tube could do in the wound.

The paper was further discussed by Professor Lavista, of the City of Mexico, and the Chairman, who claimed we had not yet reached a stage where we could be absolutely certain of the aseptic condition of any wound.

Dr. Marcy closed the discussion by saying that when closing a wound he approximated the edges of each individual structure very thoroughly.

Afternoon Session.

Report of Four Cases of Brain Surgery, read by Dr. Andrew J. McCosh, of New York City. No general conclusions can be drawn from these cases, but each one has points of special interest.

Notwithstanding the accuracy in the localization of the cerebral functions, the results of operative treatment, so far as cures are concerned, are little better than those obtained a score of years ago, and but little light has been thrown upon the treatment of epilepsy, with the single exception of certain Jacksonian cases. Each of the following cases contains some points of special interest, but no general conclusions can be drawn from them:

Case I.—Aged eighteen; extra-dural hemorrhage. Convulsions on tenth day. Trephining. Removal of clot. Recovery.

The patient, male, fell into a trench and brought to hospital eight hours afterward. Temperature, 100° F.; pulse, 76. During first twenty-four hours aroused with difficulty, then steady improvement up to end of the eighth day. On the ninth night a convulsion. Tenth

day, another convulsion with symptoms indicating pressure on the lower posterior part of the motor area of the left side.

Operation.—A button of bone was removed from over the fissure of Rolando, exposing a blood-clot. The opening was increased to two and a half inches, and the clot, three fourths of an inch in thickness at its centre, removed. The dura was not opened. The bone was replaced.

Result.—At 7 P.M. there was a slight convulsion, limited to the right leg and hand. There have been no further symptoms, and the patient made a good recovery.

CASE II.—Aged six. Extra-dural hemorrhage. Paralysis and convulsions. Trephining on eighth day. Removal of clot. Recovery.

History.—Patient fell down stairs, forty-eight hours afterward, admitted to the hospital partially unconscious. Fourth day, improvement commenced and continued until seventh day, when there was a distinct convulsion limited to the upper left extremity, lasting one minute. In the afternoon there was another convulsion involving the entire left upper extremity, and toward evening left upper and lower extremities were completely paralyzed, as well as the left side of the face, followed by two more convulsions during the night. Mental condition remained bright.

Operation.—Upon removing a button over the fissure of Rolando, a fissure of the skull was found running from above downward and backward, forming a triangle, which was cut away. The dura was rent for a space of one inch. The clot was found and removed, but no attempt made to suture the rent in the dura, as the edges could not be approximated, and the brain-tissue at this point appeared disintegrated superficially.

Result.—Upon recovering from ether there was ability to move the left arm for a short time, with a return of the paralysis as complete as before for the next twelve hours, but without convulsions. During the next twenty-four hours marked improvement began without interruption, and at the end of two weeks was out of bed, and has since remained in good health, attending school, without any return of the convulsions or paralysis.

CASE III.—General epileptiform convulsions, stupor, and delirium. Trephining in right occipital region. Œdema of brain. Aspiration and drainage (for two days) of right lateral ventricle. Recovery.

No convulsions since operation, and patient perfectly well (five months).

This patient had occasional attacks of unconsciousness extending over a period of seventeen years. There being no convulsions present, it is doubtful if the attacks were those of true epilepsy.

History.—At the age of twenty-nine patient fell down stairs and developed partial paralysis of the left arm, which gradually disappeared. He was admitted to the hospital on October 29th; November 10th he had a distinct convulsion lasting ten minutes.

No further convulsions until December 3d. He left the hospital on December 7th, but returned on January 4th. Had several convulsions up to January 25th, after which the convulsions numbered about five to the twenty-four hours.

Operation.—Although, owing to his weakened condition, operative measures were contra-indicated, yet he was losing ground so rapidly we were obliged to do the best we could. On January 31st a one and one-fourth inch button of bone was removed from over the lateral sinus. No evidence of clot was found and the pia looked normal, but there was evidence of great internal pressure, which caused the brain to bulge out through the opening even when the patient was raised to a sitting posture.

No tumor being felt, a diagnosis of fluid was made. A hypodermatic needle thrust in three different directions brought no fluid to light, but the insertion of a long needle into the right lateral ventricle disclosed the fluid. A cannula was inserted and left in place for drainage. About an ounce of fluid was the entire amount drained off, and in forty-eight hours the cannula was removed.

Result.—After February 3d the patient improved rapidly, with no signs of convulsions since, with reflexes normal, and no paralysis. At the end of two weeks patient was out of bed, but his memory of the events of the past year was defective. He made an apparent good recovery, and has been pursuing his daily labors for the past five months, free from headache or tenderness over the cicatrix. What the causes of the grave symptoms were, it is difficult to say, but I think the cicatrix in the dura was the cause of accumulation of intercranial fluid. There can be no doubt of the operation saving his life.

CASE IV.—Aged seven. General convulsions and partial paralysis of right arm and leg. Trephining. Dura opened. Thin membrane, old organized blood-clot found over motor area. Removed. Recovery. Paralysis improving, no change in convulsions (four months).

History.—First convulsion occurred at the age of eighteen months, lasting several hours, causing partial paralysis of right arm and leg for several weeks, and then disappeared. At the age of four had several convulsions. At five, very severe convulsions; since which time partial paralysis of the right arm and leg continued.

Diagnosis of pressure on the motor area of right arm and leg was made by Dr. M. A. Starr, who advised an opening to be made over the arm centre.

Operation.—A button was removed from over the fissure of Rolando, about two inches to the left of the median line. The opening was enlarged downward and forward and the dura incised.

Removal of Clot.—Lying on top of the pia was a reddish translucent membrane, which was removed. Œdema of the pia was marked.

Incision of the Pia.—Several incisions of the pia were made, allowing several ounces of fluid to ooze out, leaving the surface of the brain depressed as though the convolutions at this point were atrophied.

The dura was replaced and sutured, but the bone was not returned.

Result.—For three weeks following there were no special changes for better or worse, the convulsions and paralysis continuing as before.

It is now five months since the operation, and although the convulsions have not been modified, the child is brighter and improvement has taken place in the paralyzed muscles, but they are weak and lack proper co-ordination.

The membrane removed was undoubtedly an original blood-cot, and the most probable cause of the hemorrhage being a pachymeningitis hæmorrhagica.

Conclusions Drawn.—The mere removal of a button of bone from the skull seems to improve nearly all epileptics for a few months, and it is rather misleading to report upon the condition of these patients before sufficient time has elapsed for the disappearance of the amelioration, which may be attributed to the operation *per se*.

In the discussion which followed, DR. HEUFF, of San Antonio, cited several cases upon whom he had operated, but after being relieved for a time the convulsions returned. One case given as an illustration was that of a lady, who for about eight months after the operation was entirely free from convulsions. At the end of the eight months she came to his office, was very profuse in her thanks for her cure, became excited, and fell on the floor in a convulsion, and has had them ever since.

DR. FRANK, of Chicago, said most of his cases resulted in the same manner as those of Dr. Heuff.

DR. QUIMBY, of Jersey City, had one typical case such as Dr. McCosh's, and two years have elapsed since the operation, with no return of symptoms; but, as a rule, he thought in children the results were not good.

DR. MCRAE, of Georgia, said if we wish good results we must operate before the fits commence. He has operated on recent cases, and so far no convulsions have supervened.

Treatment of Multiple Urethral Strictures of Gonorrhœal Origin, by Combined Internal and External Urethrotomy and Vesico-urethral Drainage, was the title of

a paper read in Spanish by Dr. Juan Martinez del Campo, of Mexico. All the methods that have been recommended for the cure of multiple strictures of the urethra of gonorrhœal origin have not been followed by permanently curative results, and a relapse invariably occurred, sooner or later. This is a matter of daily observation, alike in gradual dilatation, internal or external urethrotomy.

In all my cases where I used urethral and vesical drainage subsequent to internal and external urethrotomy, I obtained better and more permanent results than could be had by any other method of treatment. My conclusions are based upon about one thousand cases, who have been kept under observation during a period of ten years, about one-fourth of whom had been operated upon by this method several years ago, and whose urethræ have been examined after a long post-operative period, and in no single instance has there been a relapse.

The permanency of the cure I believe to be due to the effect of the drainage-tube or catheter, which is allowed to remain for a variable length of time, causing an acute suppurative urethritis, which has a tendency to disintegrate the embryo-plastic tissue composing the stricture

Anæsthesia: The Technique of Chloroformization, was the title of a paper read in Spanish by Dr. Angel Contreras, of Yucatan. The author gave his experience with many thousands of cases where chloroform had been used, and his conclusions were that, properly administered, it was not a dangerous anæsthetic.

Dr. Hamilton, of Chicago, in discussing this paper, said each of the anæsthetics in use had its good and bad features. We should use that one which in our judgment appears best adapted to the individual case. If albumin is found in the urine, ether should be avoided. If there is feeble heart action, the A. C. E. mixture would be useful.

Dr. Hare, of Philadelphia, thought the profession resorted to anæsthesia too much as a matter of routine. In the last few years Dr. Montgomery, of Philadelphia, had used bromide of ethyl in several hundred cases, with satisfactory results. Dr. Hare further thought the relative value of the various anæsthetics could be settled by employing the one suitable for the individual case. In his statistics, collected from physicians all over the United States, the majority claim death in chloroform anæsthesia occurred with failure of respiration before the heart ceased to beat; and that it was the respiration and not the heart which should be watched. Personally, he thought ether was the safest and did not require such careful watching.

Dr. Randall, of Texas, said if Dr. Hare pursued his search further, he would change his mind. From his own experience he found chloroform killed by paralyzing the heart. He cited one case where the pulse had ceased and the patient was apparently dead, excepting that he still breathed. The physician administering the chloroform had watched the pulse, otherwise the patient would have lost his life. In the South we look upon chloroform as safe if the heart is carefully watched.

Dr. Ernest Laplace saw thousands of cases of chloroform administration in Europe, with but six deaths. In Philadelphia he used ether, and never saw a death from it. In New Orleans, where he used chloroform he always did it with fear as to the result. With ether in Philadelphia, he now had no fear.

Dr. Hare replied that he did not advocate ether or chloroform. In the long run chloroform was the most dangerous. He believed it killed mostly through respiration; sometimes by the heart.

Dr. Thomas H. Manly, of New York City, said ether should have the preference whenever it could be had. The number of deaths from chloroform are greater than we know of, as many of them are concealed. I have never seen a death from ether here or abroad. At present we use anæsthetics too frequently.

Dr. Quimby said, while it required less skill to administer ether, chloroform had the least effect upon the kidneys.

Torsion and Homologous Ligation of Divided Arteries, was the title of a paper by Thomas H. Manly, of New York City. Homologous ligation of divided arteries consists of a section or sections of the superfluous ends of the vessels in amputations. Then a furling and tying of the vessel on itself in such a manner as to occlude the lumen of the trunk with its own walls; a veritable living ligature. He had carried experimentation upon the dog, and made sufficient observations upon the human being to fairly test the expediency of this procedure. The ideal in the obturation of divided arteries will be attained when every description of extraneous ligature can be eliminated in amputation cases. Primary union would succeed under one dressing. Homologous ligation had its limitation, but with the utilization of torsion there is almost no artery in the body which could not be definably and permanently closed without the employment of ligatures of any sort of foreign substance. Perfect asepsis is the *sine qua non* to success in this procedure.

He adverted to the fact that modern studies have revolutionized our views on the question, the technique of the ligation of arteries; and now we did not aim to divide the internal coat or secure a clot, because it has been proven that neither is essential to effectually close the vessel's lumen.

The paper was discussed at length by Drs. Brock and Ross, of Richmond, Murphy, of Chicago, Kirnan, of Wilkesbarre, Pa., and Steman, of Fort Wayne, Ind.

Bi-lateral Perineal Incision for the Removal of Phosphatic Calculi, was the title of a paper by Dr. D. Ford, of Augusta, Ga. The patient was twenty-two years of age, whose first symptoms began at the age of nine. The diagnosis being readily made, the bi-lateral perineal operation was performed, and a large phosphatic calculus, about the size of a goose egg, weighing ℥ iij., ℥ ij., was removed.

Fourth Day, Friday September 8th — Morning Session.

Empyema and its Proper Surgical Treatment was the title of a paper read by Dr. Carl Beck, of New York City. The essential question in this paper was, which of the three methods of treatment used—aspiration, incision, or resection—gave the best result. From his personal experience, together with statistics collected, it proves resection the method of treatment for obtaining the best recovery. Resection, he found, was gaining ground daily among surgeons. Some surgeons have been in the habit of making an incision first and then use drainage for a time, and if no good results are obtained, follow it up with resection, which only causes unnecessary delay, and in many cases makes the prognosis bad. The prognosis of any case depends entirely upon the early diagnosis made by the practitioner and the method of treatment adopted by him. In using a hypodermatic needle for diagnostic purposes sometimes the pus will be too thick to flow through the needle, and in case it fails to appear, if you will unscrew the syringe, leaving the needle inserted, and then push a wire through, upon withdrawing the wire you will find the end covered with pus.

Aspiration.—Absorption can only take place under the most exceptionally favorable circumstances, therefore in the large majority of cases treatment by aspiration alone only drags the case along until the patient's vitality sinks too low for resection to save him, and it is from just such cases as these that the opponents of resection gather their statistics.

Incision.—This method of treatment will permit of drainage, but there are always adhering lumps to be found upon the surface of the pleura which no amount of drainage or washing can remove. They must be picked off with the finger.

Resection.—Is by far the best of all methods. We are

then enabled to sweep the finger around inside, opening up any pockets, and tear off all adhering lumps and thoroughly cleanse and drain the cavity. In making a resection, if the operator is careful to preserve the periosteum, the rib will grow again. After making a resection I do not immediately insert a drainage-tube. If a tube is inserted at once, owing to the fact that the movements of respiration will cause the tube to irritate the surfaces, you will cause more or less hemorrhage. I usually wait three days before inserting it.

In conclusion, I will say that resection is safe, clean, and easy to perform, and gives by far the best results. I do not, however, approve of the method of resection recently recommended in Germany.

The following papers were read by title only: "Ununited Fracture," by Lewellyn Eliot, M.D., of Washington, D. C.; "The Probable Cause of the Limp of the First and Second Stages of Hip-disease," by Harry M. Sherman, A.M., M.D., of San Francisco, Cal.; "The Treatment of Pott's Disease of the Spine," by A. B. Judson, M.D., of New York City; "A Case of Acute Arthritis of the Hip of Infants, with some Remarks on the Etiology of the Affection," by Augustus Thorndike, M.D., of Boston, Mass.; "A Contribution to Rectal Surgery," by H. M. Bishop, M.D., of Los Angeles, Cal.

After a vote of thanks by the section to the officers the session was closed by the President, Dr. John B. Hamilton, of Chicago, Ill., who thanked the members of the section for the interest manifested by them during the proceedings, and regretted the fact that owing to the regulations as to time limit in reading papers and discussions, many of the papers were cut short and not properly read, and in some few cases there was no time for discussion at all, but for this he was not responsible.

Professor Lavista, of the City of Mexico, and Dr. Rudolph Matas, of New Orleans, La., thanked the section on the part of the Honorary Presidents of the Section, and for the courtesy shown the Spanish-speaking members. The section then adjourned.

SECTION ON DISEASES OF THE MIND AND NERVOUS SYSTEM.

First Day, Tuesday, September 5th.

Dr. C. H. Hughes, of St. Louis, President, in the Chair.

Address of the President.—After welcoming the members present, and before proceeding to the scientific work of the section, he noted some of the neurological advances of our day, and especially the contributions of neurology to general medicine and the consequent welfare of the world. He referred at length to the brilliant achievements of American neurologists, and gave a brief historical sketch of the work accomplished during the present century. In conclusion, he said that America breeds and develops neurologists as the water breeds and develops fishes. The pabulum neurology feeds on is in the American people—their hustling, rushing habits, their business, professional, social, and political environment, and the numerous newspapers they read every morning before breakfast and every night before they forget to say their prayers—this moral, political, social, and business atmosphere of ambition and bustle, tends to develop the strongly endowed, neurologically and psychologically, as it tends in the weakly endowed to the development of neuropathic conditions. It develops neurologists and psychologists to care for the neuropaths. It builds and it breaks the nervous system. It cannot yet be said that we are a neuropathic people, though we are tending that way; but neurology is advancing with equal pace with neuropathic break-down, and will, it is hoped, ultimately enlighten and save the people from their neuropathic sins.

Dr. William A. Hammond, of Washington, D.C., then delivered a short address in Spanish, which was responded to by Dr. Manuel Carmona y Valle, of the City of Mexico.

Cerebral Spastic Paralysis in the Adult.—Dr. Carmona then read a paper with this title.

The Prognosis of Railway Spine. by Dr. F. X. Dercum, of Philadelphia. He described briefly a case in which a blow to the back had been followed by the usual symptoms of painful back associated with neurasthenia and hysterical symptoms. The case was considered as a typical "Railway Spine" so-called, without the element of litigation. It was therefore considered as a suitable case upon which to test the possibilities of the rest cure, and which might perhaps enable us to answer the question so often asked of the expert in court: "Will the patient recover, and if so, how long a time will it require?" After five and a half months of treatment in a special hospital an almost complete recovery ensued. The medico-legal value of the result was also considered.

Dr. Brower, of Chicago, thought that the paper presented many valuable suggestions as to diagnosis. The cases of "Railway Spine," as seen in Chicago, seemed to be of a different character. There were not so many objective symptoms. The symptoms in Dr. D.'s case were undoubtedly either of neuritis or meningitis.

Dr. Fuller, of Grand Rapids, had seen a case with similar symptoms repeatedly relieved by opening the spinal canal and evacuating some of the accumulated fluid.

Dr. Dercum, in concluding, said he had seen many cases in Philadelphia. He thought the muscles and ligaments suffer most, and that the psychic symptoms indicated neurasthenia.

Treatment of Cerebral Hemorrhage.—This was the title of a paper by Dr. D. R. Brower, of Chicago. He referred to the various methods of treatment with the view of controlling arterial tension and diminishing arterial degeneration. He also spoke of strychnine and the application of the galvanic current to the brain for the relief of the hemiplegia.

Dr. W. M. Leszynsky, of New York, said that the subject was of the greatest importance to the general practitioner, and it required a comprehensive knowledge of general medicine to manage this class of patients. He thought that such a complication as anchylosis of the shoulder-joint was generally avoidable in hemiplegics if passive motion were begun early.

Dr. Hare, of Philadelphia, did not believe that the galvanic current acts directly upon the brain structure, but may hasten absorption in a reflex manner.

Dr. Carmona, of Mexico, considered electricity of no value when secondary degeneration has occurred.

Dr. Roque Maconzet, of Mexico, was of the same opinion.

Dr. Dercum opposed the use of strychnine on account of the probability of hastening contracture. He agreed with Dr. Hare in reference to the use of electricity.

Dr. Hughes thought that galvanism does not always produce its direct action on the brain, but it is not impossible for the current to pass directly through the brain in the living body.

Dr. A. D. Rockwell, of New York, believed that the symptoms produced seemed to indicate that the current acted directly on the brain.

The discussion was closed by Dr. Brower.

Second Day, Wednesday, September 6th.

Morning Session.

Organic and Mental Co-ordination.—Dr. William Fuller, of Grand Rapids, read a paper with this title. The intention of the writer was to point out the relations existing between the nutritive conditions of the organs of the body and the mental feelings related to the individual organs, which are not only co-ordinated in their nutrition from the blood, but are also co-ordinated by nervous connections so as to produce a frame of mind which cor-

responds to the general nutritive condition of the organs of the body as a whole. The practical conclusion is that the mind may be influenced by alterations of the physical processes and that the nutrition of the body is influenced by the mental states of emotion and belief. Illustrations were made in support of the theory advanced. In the opinion of the writer the cerebellum is the brain of the organic nervous system, and though it is not the seat of the emotions, which are conscious feelings, and properly belong to the cerebrum, yet these feelings are produced by cerebellar states.

Dr. Brower said it was to be regretted that Dr. Fuller did not give his reasons for assigning functions to the cerebellum which were attributed to it many years ago.

Should Inebriates be punished by Death for Crimes committed while Intoxicated?—This paper was read by Dr. T. D. Crothers, of Hartford, and the following conclusions were drawn:

1. The legal treatment of insanity has changed in obedience to a more accurate knowledge of the brain and its diseases.

2. The legal treatment of inebriety is unchanged to-day. Although it occupies two-thirds of the time of courts, all teachings of science and a larger knowledge of the inebriate and his malady are ignored.

3. The ruinous error of punishment by fines and imprisonment of inebriety, and petty crimes associated with it, which notoriously increases and perpetuates the inebriate and criminal, is a fact demonstrable in every community.

4. Thus public opinion, through mediæval theories and laws, is training and preparing a class of inebriates who first commit petty, then capital crime, with a certainty that can almost be predicted.

5. The death-penalty for such crime utterly fails for the same reason. The execution of any number of this class simply opens the door for an army already prepared and trained to take their places.

6. From a scientific study of these cases, it is clearly apparent that they are diseased and incapacitated to act sanely. Alcohol has palsied the brain and made them madmen. The very fact of continuous use of alcohol is evidence of mental impairment and unreasoning act and thought.

7. To hold such men accountable for their acts, and by punishment expect to deter them from further crime, and by such punishment check others from similar crime, is an error which both scientific teaching and experience point out.

8. The object of the State, through the law, is to protect society and the individual; but if the execution of the law-breaker fails to accomplish this end, the laws are wrong.

9. The unfounded fear that the plea of insanity in crime, and the failure to punish, is an encouragement for further crime, is flatly contradicted by statistics.

10. Among the mentally defective, the insane, and inebriates, the death-penalty is followed by an increase rather than a diminution of crime.

11. The inebriate should never be hung for crime committed while under the influence of alcohol.

12. This method of punishment is never deterrent, but furnishes an attraction for other inebriates who commit similar crime in the same way, following some law of mental contagion.

13. The inebriate murderer should be confined the rest of his life in a military work-house hospital. He should be under the care of others, as incapacitated to enjoy liberty and incompetent to direct his thoughts or acts.

14. A change of public sentiment and law is demanded, and a readjustment of theory and practice called for. The criminal inebriate occupies a very large space among the armies of the defective who threaten society to-day, and his care and treatment must be based on accurate knowledge, not theory.

15. Inebriate murderers should never be placed on public trial, where the details of the crime are made prominent or the farcical questions of sanity are publicly tested. They should be made the subject of private inquiry, and placed quietly in a work-house hospital, buried away from all knowledge or observation of the world.

16. The contagion of the crime and punishment would be avoided, and the inebriate's services might repair some of the losses to society and the world.

New Process for Extracting the Essential Principles of Certain Animal Organs, and on their Physiologic and Therapeutic Properties.—This was the title of a paper read by Dr. W. A. Hammond, of Washington, D. C., with the following summary:

1. It is possible, by the process described, to obtain from the tissues of the various organs of the body, such as the brain, the heart, the spinal cord, the testes, the ovaries, the muscles, the thyroid gland, substances which are possessed of powerful physiological and therapeutical properties.

2. There is much evidence to show that the active principle of each of these animal extracts acts by preference on that organ of the body which is analogous with that from which it has been derived. Thus, "Cerebrine" particularly affects the brain; "Medulline," the spinal cord; "Cardine," the heart; "Testine," the sexual system of males; "Ovarine," the sexual system of females; "Musculine," the muscles; "Thyrodine," the thyroid gland, etc. And this not only physiologically, but to some extent, at least, in suitable cases, therapeutically.

3. It is not yet determined whether the active principle (or principles, for there may be more than one agent in each) exists primarily in the organs acted upon by the menstruum, or is a secondary product of the nature of leucomaine. They all act, in the first place, as disturbers of the vaso-motor system, some of them producing a paralyzing, and others a spastic effect.

4. Neither is it always the case that this effect is the same in all instances with the same extract. Thus, "cerebrine" although generally causing a sensation of fulness in the head, slight headache, flushing of the face, suffusion of the eyes, etc., sometimes produces paleness, slight vertigo, and a sensation of faintness.

5. This variability is apparently due to the size of the dose, the state of the system at the time of administration, or the nature of the disease for which the extract is given. In these respects there is an analogy with the action of other substances used as medicines, and with that of certain remedial agents. Among the first named are opium and its active principles, quinine, cocaine, alcohol, etc.; among the latter, electricity, heat and cold, massage, exercise, etc. In the use of these extracts, as well as in the employment of every therapeutical agent, it is necessary for the physician to familiarize himself as thoroughly as possible with the constitution, habits, and inherent proclivities of his patients.

6. No ill effects, general or local, have ever in my experience followed the administration of any of these animal extracts, whether they have been given hypodermically or by the mouth. The dose is so small that when taken upon the tongue it cannot be swallowed, but is absorbed rapidly from the mucous membrane of the mouth.

7. Finally, while it is too soon to obtain definite results relative to the effects of these extracts in curing organic diseases, there is abundant evidence to show that they exert a beneficial influence in such affections, and that they are rapidly curative of many so-called disturbances. This is especially the case in regard to "cardine" in certain cardiac disturbances, "cerebrine" in nervous weakness (neurasthenia), and "testine" and "ovarine" in aberrations of the sexual system in males and females, respectively.

Dr. C. H. Hughes thought we were in danger of falling into the same attitude of scepticism in this matter as was shown toward Jenner, Morse, and Cyrus Field. He looked forward to great possibilities from the employment of animal extracts.

AFTERNOON SESSION.

Symptoms and Treatment of Partial Epilepsy.—This paper was read by DR. ROQUE MACONZET, of the City of Mexico. His method of treatment was governed entirely by the cause of the disease. He believed that anti-syphilitic medication is often useless and surgical interference becomes necessary.

DR. RICHARDSON, of Columbus, O., thought the treatment advised by Dr. Maconet was the only rational and accepted method, and was fully abreast with the times.

DR. BROWER, of Chicago, thought the operation *per se* was insufficient to cure, but is merely an adjunct to constitutional treatment.

DR. DERCUM, of Philadelphia, said these operations had been done frequently in his city, with much benefit but without absolute cure. In the main he agreed with the previous speaker.

Erotopathia.—Morbid Erotism.—DR. C. H. HUGHES, of St. Louis, read a paper with the above title, and formulated the following conclusions:

1. Morbid erotism presents both normal and abnormal psychological aspects. It, therefore, presents a voluntary deviation from the ordinary and natural indulgence of the genesic instinct—the normal, but immoral, psychology of the eroto-sexual propensity, and instinctive, inherent, organic, dominant, and often resistless, involuntary perversions of this passion; the latter being the true abnormal and organically unnatural sexual perversion, the reverse, or contrary sexual instinct. This is the psychiatrical aspect of the subject, the one that most concerns us as alienists and neurologists.

2. Love and the genesic sense are not one, as is shown in the antedating of love to the appearance of the sexual feeling, in the developmental period up to puberty, and its survival beyond the menstrual climacteric in women. In the organic evolution of the individual, love antedates the birth and survives the decay of the sexual feeling, though it is intensified or diminished, or otherwise modified or influenced by sexual states.

3. The duty of the hour is to search out the complicating neurological and neuropathic factors, and the predetermining neuropathic conditions, the neurology and neuriatry, immediate and ancestral, of these unique morbid and unnatural eroto-genesic perversions; to weigh in conjunction the potentialities of physical or psychical environment, and determine as satisfactorily as we may, in the light of clinical and historic facts, and physiological and pathological states, the true mental status of the eroto-sexual pervert.

4. This inquiry involves a study of hystero-erotic attachments and aversions, erotic trances, ecstasies, beatitudes, divine amours, immaculate conceptions, etc.. as well as the true contrære sexual empfindung or psychopathia sexualis. It involves also certain morbid erotic perversions sometimes observed in epileptically insane females, such as vaginal mutilation with glass, pins, and needles inter vaginam, etc., epileptic and neurasthenic exhibitions, etc., during a psychical equivalent. We include all under erotopathia.

In every study of morbid erotism the distinction between love and lust should be sharply drawn, as between healthy erotism and perverted or debased sexual passion. This is necessary to a proper understanding of those historical and every-day recorded instances of pure but perverted Platonic affection, and those oft-recurring and startling reversions of sexual love into murderous hate and passion, so often chronicled in the public press.

While science should cast the mantle of charity over morbid impulsions yielded to in resistless psychopathic states, it must draw the line between similar impulsions (depraved and but slightly, if at all, morbid) cultivated and gratified in normal psychical conditions. It must separate disease from depravity of mind, and herein lies the difficulty of our subject.

The question of crime and insanity, often difficult to solve, devolves upon us as medico-jurists to determine from known and yet to be acquired psychologic and psychiatric data.

The subject is primarily neither one of sentiment nor morals exclusively, but mainly one of psychiatry, to the study of which the data of alienism and psychology should be rigidly applied in all questions of medical, moral, and forensic inquiry.

DR. T. D. CROTHERS, of Hartford, said that with the array of symptoms as outlined, it is impossible to consider such cases other than insane.

DR. J. K. KING, of Watkins, N. Y., considered the difficulty arose in determining where moral depravity ends and insanity begins. He cited illustrative cases, and concluded that all could not be classified as insane.

DR. MACONZET, of Mexico, expressed the view that erotopathia may be produced by either peripheric or centric causes. He had seen several cases in women. Some were occasioned by disorders of the genital apparatus, but in others no physical deformity was found.

Treatment of Nervous Diseases in Sanitariums.—This was the title of a paper by DR. J. K. KING, of Watkins, N. Y.

He said there was great danger at the present day of specialties being too much divorced from each other. He made a plea for their closer union, and more harmony in treatment. This is best accomplished, especially in chronic nervous diseases, in medical institutions. The various requisites necessary to make a sanitorium more than a sanitary resort, and to make it worthy of the confidence of the medical profession, existed in the varied methods of treatment and the advantage of constant supervision. He also discussed the great advantage of occupation, regularity of life, and healthful surroundings in addition to systematic treatment.

Diseases of the Gangliated Nerves.—This paper was read by DR. CHARLES K. MILLS, of Philadelphia. He first referred to the erroneous views as to the gangliated nerves. Even to the present day fanciful views regarding the so-called sympathetic nervous system are held by the profession at large, which was in part his reason for presenting this paper to the section. The name "sympathetic" has had much to do with perpetuating these errors. He argued that the ganglia of the gangliated nerves constitute lower, local, decentralizing levels of the nervous system. He gave the following as the diseases which may be regarded as genuine affections of the gangliated nerves:

1, Certain vaso-motor neuroses of the extremities, as erythromelalgia, digiti mortui (dead fingers), Raynaud's disease, or symmetrical gangrene, angio-neurotic œdema, and some forms of acro-paræsthesia; 2, certain local vaso-motor and trophic affections, as perforating ulcer of the foot, Morvan's disease in some instances, and various pigmentary and other skin affections; 3, unilateral and localized sweating; 4, some forms of pupillary dilatation; 5, tachycardia and probably other varieties of disorder of heart rhythm; 6, some varieties of changed arterial tension; 7, anasarca, from deficient vaso motor tonus and unassociated with organic disease of heart or kidneys: 8, some varieties of arthropathy: 9, some varieties of lymphopathy; 10, some forms of isolated and diffused neuritis, as of the cervical gangliated cord of the great and lesser splanchnics, or of the pelvic splanchnics, or nervi-errigentes; 11, some painful sensory disorders not neuritic in character, but which give rise to mediastinal, pulmonary, abdominal, and pelvic neuralgias; 12, probably various reflex disorders.

The Modern and Humane Treatment of the Morphine Disease.—DR. J. B. MATTISON, of Brooklyn, read a paper with this title. Attention was called to the lamentable fact that morphinism finds its favorite victims among our own profession.

It was, therefore, quite natural to suppose the subject would be found of interest to a Congress of medical men.

The modern treatment of the morphine disease is compassed, mainly, by three drugs—bromide of sodium, co-

deine, and trional. These form a combination of unrivalled efficacy, if properly used, in proper cases, and, combined with minor aids, make a method far in advance of any yet presented, to secure two leading objects—minimum duration of treatment and maximum freedom from pain.

The humane feature of this modern method is of marked and far reaching importance; for, by it, the common idea that escape from the bondage of opium is possible only through great and prolonged distress, has been proven to be a mistake, being largely robbed of its terrors: and when this humane treatment shall come into general practice we shall note a largely increased number of ex-poppy habitués.

Few advances in modern therapeutics have been more marked than along the line of this disease; and never was its treatment so simple, satisfactory, and successful as now.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

DUCKWORTH'S DEFENCE OF MODERATE DRINKING—THE SELECT COMMITTEE ON MIDWIVES—SMALL-POX—PROFESSOR CHARCOT—MEDICAL QUESTIONS IN PARLIAMENT—SALE OF POISONOUS PROPRIETARY ARTICLES—QUARANTINE—TUBERCULOSIS COMMISSION—VACCINATION—HEALTH OF THE ARMY—HOMES OR COLONIES FOR EPILEPTICS—INFLUENZA—MEDICAL DEGREES FOR WOMEN—APPROACH OF CHOLERA—SMALL-POX—TYPHOID.

LONDON, August 19, 1893.

THE sarcastic Frenchman who defined an English summer as "three hot days and a thunderstorm," ought to have been made to pass a month out of the last three in our "tight little island." From every direction the stories of the results of the great "heat-wave" through which we are passing are oppressive, and here in London we are suffering as no one can remember from excess of sunshine and sun heat. Meteorologists tell us that we are in the midst of an enormous area free from cyclonic disturbances. As the accumulation of heat depends on the distribution of atmospheric pressure, this accounts for the condition from which we are suffering, but as we cannot alter the conditions we can only resolve to endure.

I have spent some time in warmer and sunnier climes, but scarcely remember to have felt the languor and oppression experienced during the past week. The thermometer was only 82° F. in the shade this morning, though it has been 90° in some places. I am writing in a north room with open windows well shaded with heavy blinds and curtains, and the thermometer is just under 80° F., but in other parts of the house it is higher. Many cases of heat-stroke have occurred, and other effects, as diarrhœa, exhaustion, heart-failure, etc., make a considerable part of practice. Horses too are suffering, and the omnibus companies are changing the usual order of their work.

The treatment of inebriates continues to occupy attention. Not long since it was the report of the Departmental Committee, and now it is the issue of the evidence taken. The first witness was Dr. Hoffman, who is Inspector of Retreats under the Inebriates Act. He considered that an extension of the system of retreats, especially for the poorer classes, is very desirable. He found the poor had not much chance of a share in the benefits of retreats. He advised separate small retreats in preference to large institutions, and thought that on the expiring of the term patients should be allowed to re-enter by their own voluntary act, and so prolong the period of treatment.

Dr. Norman Kerr opposed the notion that the loss of self-control was greater on the part of a woman who took to drink than on the part of a man. He said he could name ladies in society who had been in "Homes," and who under his sanction had returned to their own families, and were now discharging all their duties in society simply by the reassertion of their wills, which had been paralyzed by drink—some for as long a period as ten years.

Sir Richard Quain thought that drunkenness accompanied by injury to a man's self or his family ought to be an offence punishable by imprisonment or otherwise. He had seen drunkards managed by their own families recover, but they would be much more likely to do so under the control of a retreat. He remembered two distinct cases—one, the son of a distinguished member of Parliament, who quite recovered by voluntary total abstinence.

Sir John Bridge, whose experience as a magistrate is very large, pointed out that there is power to compel an habitual drunkard to find sureties for six months, and he thought this provision of the law should be acted on. He thought it important that the public should come to see that repeated drunkenness is a crime, and a prison is the place for criminals. It would be mischievous for people to say "Oh! they make these drunkards very comfortable." It is an offence which is injurious to society, to a man's friends, to himself, and however looked at, this is crime, and should be treated as crime. Again, he held that all crime is apt to become habitual: a burglar becomes a habitual burglar; a pickpocket is always a pickpocket; all crimes become habitual. To prevent drunkards habitually offending, Sir John would treat them as other criminals. In a bad case, when a man's physique is gone, he compelled them to find sureties for six months or go to prison. Then when they came out he heard no more of them.

Colonel McHardy, prison commissioner for Scotland, advocated normal treatment as far as possible. If a man's friends could not look after him, nor any association for aiding discharged prisoners, he would have him detained in some establishment, and suggested that spare space in workhouses might be utilized.

It is obvious that the views of these witnesses represent opposite methods of dealing with an acknowledged evil. The medical men look upon alcoholism for the most part as a disease, the magistracy regard it rather as a crime. If drunkenness be made punishable before it becomes habitual, there will be less excuse for separating it from other offences against society, and treating it as insanity or providing comfortable retreats. If, on the other hand, drunkards are to be free to indulge their appetites until they cannot control them, there will be greater need of imposing restraints on them at that stage. The recommendations of the committee will doubtless receive every attention, and one of them is the provision of reformatory institutions aided by contributions from imperial or local funds. This, I may remark, seems much like a proposal to saddle the overburdened rate-payer with the cost of maintaining drunkards in comfortable homes or retreats, while their families are already too often "on the rates." The government is deeply pledged to early legislation on the temperance question, but whether it will have an opportunity of redeeming the pledge is very doubtful. Even if it should, the task of carrying a measure which will excite so much controversy will be no easy one. Everyone admits that drunkenness is an offence against society, but many hesitate to translate that phrase into the word crime, and those who admit the word seem to think it is of a nature that calls for different treatment from that awarded to other offences.

In connection with the subject, I may mention that a London physician has gone over to The Hague to defend moderate drinking before the International Congress against the abuse of alcohol. From a telegraphic summary now before me, Sir D. Duckworth seems to have taken up the same position which he tried to maintain on a former occasion in this country. He found very few

supporters, and at the conclusion of his paper hisses freely mingled with the usual applause. One member, in support of moderate drinking, said "men could not do without a stimulant"—so my telegram says—but surely the teetotallers, as well as the Mohammedans and other races who refuse to drink, are a standing proof of the fallacy of this assertion. Sir D. Duckworth has been treated to such caustic logic at home that I hardly expected him to go abroad for the sake of repeating his views; and I cannot help thinking that, when opposing total abstinence, he would have shown better taste by declining the office of vice-president for England of an anti-alcohol congress.

The report of the select committee of the House of Commons on midwives has been issued. From the evidence taken at the four sittings held, the committee conclude that midwives are a necessity, that their work heretofore has been, on the whole, successful; but that many deaths, maternal and infantile, have been caused by the want of training of midwives. They advise that a register should be instituted and the term "Registered Midwife" should be protected, and restricted to those who have been properly trained—the vested rights of those now in practice being preserved by permitting the use of the term midwife without the magic prefix "registered." A system of training, examination, and registration is recommended to be regulated by the General Medical Council, or if that body declines the honor, the Privy Council to make arrangements. Any local provisions to be carried out by the county councils. The committee do not believe that the creation of a class of trained midwives will be injurious to the medical profession, but already there is evidence that they may be mistaken in this. The statements made by witnesses on this point may be correct from the point of well-to-do practitioners, but those who now supply the poorer districts declare that the sacrifice of the midwifery branch, and all that will be sure to go with it, will so restrict their earnings as to make living impossible.

Small pox is still on the decline. The death of Professor Charcot is announced. He took refuge in London with his family during the siege of Paris and resided with friends of mine, so that I had full opportunities of knowing him. Since then what an amount of good work he has accomplished! His methods did not always commend themselves to English judgment, and I have in a previous letter expressed some disapproval of them, but everyone recognized in him the scientific spirit and the devotion to work which has carried his fame throughout the civilized world.

London, August 26, 1893.

Some medical matters have managed to obtain a moment's hearing in Parliament amid the political conflicts, but only in the form of questions. Thus ministers have replied that sanitary control of the great fairs in India has been beneficial, and this year the great fair at Hurdwar had passed off without spreading cholera. As to the gatherings at Moslem holy places, as far as acceptable to the Porte, assistance would readily be given to prevent outbreaks of cholera at Mecca, Medina, and the Red Sea ports.

Ministers were obliged to admit on Monday that the Attorney-General had given directions to the Public Prosecutor, limiting actions against patent-medicine venders to cases in which the articles contained sufficient poison to make them distinctly poisonous. The question seems to have been provoked by a case lately before the courts. It is a dangerous thing to permit the sale of articles containing minute quantities of poison, as the continual holocausts of babies to soothing syrups fully proves. There was recently a prosecution for selling a "skin lotion" which was laden with corrosive sublimate, and yet warranted to contain nothing injurious, and to be a certain beautifier of ladies' faces.

Another question in the House elicited the fact that the Quarantine Acts are now under the control of the Privy Council, and that England will not resort to quarantine except for yellow fever and plague, and then only in cases when otherwise ships from England would be treated by other countries as liable to quarantine in consequence of the omission.

It was stated on Tuesday that two of the inquiries undertaken by the Bovine Tuberculosis Commission were completed, and that the third would probably be finished by the end of next month; after which, I presume, we may look for the report.

The Home Secretary, in reply to another question, said he strongly deprecated second prosecutions for non-vaccination. He has brought in a bill to prevent this. It looks like giving the anti-vaccinationists the option of a fine or vaccinating their children. Is it not a license to them to propagate small-pox among their neighbors in consideration of a trifling payment? And this in spite of the recent diffusion of small-pox through the country.

The report of the Army Medical Department for 1891 has appeared, and gives an account of the health of our army during that year. I think these blue books are less interesting than formerly. They used to contain some interesting contributions from army surgeons on subjects on which these officers had opportunities of work which their civilian brethren to a considerable extent lacked. These valuable essays are now omitted, and it requires a rare appetite for statistics to enable a civilian to digest the mass contained in any year's report. In our home army it is satisfactory to notice a decrease in the death-rate as well as in the average time of inefficiency from sickness. Scarlet fever prevailed at Aldershot, and in a less degree at other stations. There were altogether 215 cases, but only 3 deaths. Measles also prevailed, but no death is reported. There was one case of small-pox. There were 17 deaths from typhoid fever; in the previous year there were 30. The attacks were 109 and 136, respectively. Dublin had 30 cases, 2 fatal, and the disease appeared in all districts, though in some there were only one or two cases. Influenza, which was epidemic throughout the kingdom, also affected the troops. The venereal diseases show a decline of 35.9 per 1,000, on the average, for the last five years. There were more suicides than the average for ten years—25 as against 20. The average age of these was twenty-nine, and their service ten years.

What should be done with epileptics? The question grows in urgency. The poor when afflicted have their lot made very hard. Employment is frequently refused to those only slightly afflicted, on account of the uncertainty, and often danger, that would be introduced. To consign them to pauperism or shut them up in asylums is alike costly and useless. Homes have been proposed, and in some cases would be useful, but those who have seen the "Colony of Bethel," in Germany, report most favorably of the plan. Work adapted to each patient is the leading idea. Regular occupation is provided, and this seems to add to the pleasure of life of the patients, who are certainly happier than under no system at all. As an indication of the variety of employment which epileptics can engage in, I may mention that the German colony manufactures chemical products—makes its own bromide and exports it. There are about fourteen hundred patients in the colony. The foundation-stone of the church was laid by the Emperor Frederic. I am not able to give figures as to the financial state of the colony, but those who have advocated homes in various towns might well consider whether something of this kind, "far from the madding crowd," would not be a better solution of a difficult problem.

A further report on epidemic influenza has been published by the Local Government Board. It contains another paper by Dr. Parsons, who prepared the volume issued in 1891, as well as a report on the pathological aspects of the disease by Dr. Klein. There is also a prefatory summary from the pen of the chief medical officer, Dr. Thorne Thorne. I must recur to this interesting report another week.

The ladies have scored again. The ancient University of St. Andrew's has resolved to recognize the London

School of Medicine for Women. This will enable the students of that school to graduate at the University of St. Andrew's, and from the manner in which women students have seized every opportunity of obtaining academical distinctions, we may expect soon to find a number taking medical degrees at St. Andrew's, and carrying off their full share of honors and prizes.

Cholera steadily approaches. There have been some cases of acute gastro-enteritis in London, and one or two deaths of so suspicious a character as to be treated by disinfection and all precautions. A bacteriological investigation of the cases is to be carried out by Dr. Klein. Medical men do not attach great importance to these cases, but the public is naturally alarmed. At our ports there have been cases brough to us, but isolation and disinfection under the medical officers have prevented the disease from spreading.

Small-pox continues to abate. There is a diminution of enteric fever, and the general state of the public health is satisfactory.

WHAT A NATIONAL BOARD OF HEALTH MIGHT DO.

To the Editor of the Medical Record.

Sir: The bill to be introduced in the U. S. Senate for a provision of a National Board of Health is an excellent measure, but it overlooks an abuse which might, or should, come within the scope of such national legislation, viz., the anomalous condition of the laws of the different States governing medical practice. This question has heretofore been left to the State legislatures, and the result is a great diversity of laws, or no law. Ignorant charlatans can buy a parchment from one of the bogus diploma factories, and go to certain States and practise medicine without molestation. The penalty for issuing such bogus diplomas—six months' imprisonment and a small fine—is wholly inadequate to prevent their sale and use, to the hazard of the health and the lives of the people.

Another abuse which should come under the supervision of a National Board of Health is the manufacture and indiscrimiate sale of patent medicines. The people who are induced by the seductive advertisements of these nostrums to buy and use them, know nothing of their contents, nor whether the medicines are suited to their ailments. It would be better to wholly prohibit the sale of medicines in that way, but failing in that, the proposed National Board of Health should have power to supervise the business of preparing, should analyze and ascertain their constituents, and determine whether they are harmful, or beneficial, or useless.

Leonard Landes.

58 Rivington Street.

A Female Sanitary Inspector.—The Brighton (England) town council have taken a new departure in their sanitary work by appointing a woman as an inspector of nuisances for the borough. For the present the appointment is for three months, at one pound per week. Her duties will be to visit the houses of the poor in which cases of children's ailments occur. The candidate appointed has been a district nurse in Brighton, and has also been at St. Bartholomew's Hospital as a nurse for two years, in addition to having been a nurse at the County Hospital and the Brighton Workhouse.

Preconceived Ideas.—One can do nothing without preconceived ideas; but we must have the wisdom to believe in their deductions only so far as experience confirms them. Preconceived ideas, under the rigid control of experimentation, are the vivifying flame of the science of observation; there are no fixed ideas. The greatest disordering of the mind is to believe things are because one wishes them to be. To enter upon a path and to stop every moment and make sure you are not going astray—that is the true method.—*Pasteur.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 9, 1893.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	26	7
Scarlet fever	22	1
Cerebro-spinal meningitis	4	10
Measles	57	2
Diphtheria	75	24
Small-pox	12	2
Cholera	0	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

The Relationship of the Nose and Rectum —We have been gradually initiated into the belief that certain forms of intra-nasal disease may be associated with more or less distressing disturbances of the respiratory function; but now we are invited to extend the sphere of the rhinologist to the genito-urinary and rectal organs. This, at least, is the tenor of an article by Dr. J. G. Carpenter, in the *Medical Mirror*. Lest his readers should underrate the pathological importance of naso-pharyngeal catarrh, he points out that "the sequels of naso-pharyngeal catarrh are: Reflex cough, sneezing, stenosis of nasal cavities, ocular catarrh, asthenopia, aural catarrh, headache—frontal, vertical, or occipital—nasal polypi, tonsillitis, enlarged tonsils, hypertrophy of the submaxillary, anterior and posterior cervical glands, patulency of the Eustachian tubes, hemorrhage of the throat—either the naso-pharynx, larynx, or trachea—epistaxis, laryngitis, tracheitis, bronchitis, and catarrhal phthisis, neuralgia, or numbness of the limbs or trunk, anæsthesia, hyperæsthesia of the skin, paresis of the arm and forearm, dyspepsia, hay fever, irritability, melancholia, frightful dreams, agoraphobia, partial loss of memory, or intellectual faculty, insanity, insomnia, vertigo, palpitation of the heart, neurasthenia, stammering, suicidal tendency, asthma, chorea, epilepsy, loss of taste, anæmia, anorexia, deafness, reflex irritation of the genito-urinary organs, an abundant discharge of nasal mucus or sneezing during coitus, aphonia, erythema and herpes of the integument and lining of nose, tinnitus aurium, otalgia, dysphagia, and constipation. In cases of naso-pharyngeal catarrh of long standing there is a tendency to catarrhal inflammation or debility of all the mucous membranes of the body." This is a good large order, but by no means limits the author's draft on our credulity. He instances cases in which vocal defects yielded only to treatment directed to the endometrium, and others in which spasm of the glottis followed intra-uterine applications. In quite a large number of instances laryngeal was found to coincide with rectal disease; but it seems to us that the author insists too much on mere coincidences. It is only necessary to carry this line of argument a step further to prove its inconclusiveness, as, for example, when one calculates the proportion of widows among the patients. Yet it does not occur to the author to suggest that naso-pharyngeal catarrh has any etiological bearing in respect of widowhood. Why not? Decidedly rhinological ambition soars too high, for its adepts would fain monopolize the whole field of medical practice. It is time that Mrs. Partington was put forward with her broom to stem the tide of "generalization by specialists."—*Hospital Gazette.*

The Causation of Anæmia and the Blood-changes Produced by Uric Acid.—Dr. Alexander Haig read a paper on this subject at the recent meeting of the British Medical Association. He pointed out that his previous

researches on "anæmic attacks," paroxysmal hæmoglobinuria, splenic leucocythæmia, chlorosis, and anæmia showed that these troubles are very commonly associated with excess of uric acid in the blood and urine. The excess of uric acid is not the result of the blood-changes, but their cause; for the uric-acid fluctuation begins before there are any blood-changes. The speaker said that he had the power by influencing the solubility of uric acid to bring it in excess through the blood into the urine at pleasure, and it is also possible to increase the uric acid in the blood and urine by taking a known quantity by the mouth. Applying this knowledge to the experimental production of blood changes, he said the value of the blood fraction $\frac{\text{Hæmoglobin}}{\text{Red cells}}$ varies with the amount of uric acid passing through the blood from day to day; and by intentionally increasing the amount of uric acid, definite and distinct falls in the value of the blood fraction can be produced. Uric acid is more powerful than iron, and when in excess in the blood will prevent iron from raising the value of the blood fraction; hence the observation of Murchison, that iron will not act when the liver is out of order, for dyspepsia entails an excess of uric acid in the blood. Others have produced similar blood-changes by the administration of thyroid extracts, which are rich in extractives closely related to uric acid; and a patient under this treatment gave undoubted clinical signs of uric acidæmia. The author explained by means of this uric-acid causation the anæmia and chlorosis in girls, and the relation of these troubles to the function of menstruation; also the similar effect of fevers, tropical climates, and diet. As a result of these observations he drew the conclusion that anæmia can be prevented by taking care not to introduce an excess of uric acid into the body, and can be cured by clearing it out of the blood.

The G.-T.-R. Doctor.—The frantic scramble for money in the commercial world is often regardless alike of the method of attainment, the use to be made of it, and the quality of personality of the man that secures it. Up to the present time the medical profession has set its face sternly against the plan of acquiring medical success by the means plainly dominant in politics and finance. But it cannot be denied that the Get-There-Regardless Doctor has arrived. The patient, thorough-going young physician, content to advance slowly and by gentlemanly methods along the road of experience and spontaneously given confidence, is having more and more difficulty to keep head against the splurgy, dashy fellows who use all the arts of politics to win what is called success. For these pseudo-physicians, their profession, instead of being a means of furthering human progress, is a mere tool for furthering their own progress; instead of desiring to cure disease and give their patients health for the sake of their patients, they desire to do these things for the sake of fame and self. Now, every honest man knows the two things are wholly unlike, and it is only the "business doctor" that says the science and art of medicine is the science and art of egotism. To administer a hospital or dispensary, for example, for the benefit of medicine and of the patients, is a very different affair from that of its management for the success of the physician in charge. One of these very successful practitioners once advised the writer to have big reception-rooms at the private office and to keep them running over with hospital dummies. To have well-digested knowledge to teach, and to desire to train young minds for their life-work, are very different things again from a desire to pose as professor and gain consultation-practice and money thereby. Hence the G.-T.-R. Doctor compiles big books with material borrowed from the works of other men, and storms the doors of fame with the eloquence of inexperience and the assurance gained from knowledge memorized last evening. Reports of his brilliant and superhumanly skilful operations somehow creep into the newspapers, together with his testimonials to elegant pharmaceutical preparations, the records of his goings and comings, of his opinions as to the cholera and as to the day's medical fad or scandal. All this and more, such is "enterprise," and the "hustler" finally comes to have something like a serious belief in himself and even in his own seriousness. One fine day, however, he runs afoul of some man who cannot be bribed, bullied, or deceived, some fact that does not get out of the way, that cannot be avoided, climbed over, or crushed down. Other facts of the kind do multiply, and, instead of a Napoleonic dash before an admiring world, it slowly comes about that even the poor sort of success desired is somehow missed; and by-and-by, in a few years, a few—or more—it is found that it would have been a far better policy to have desired an honorable success and by gentlemanly methods. It needs only a short residence in any large city to watch the dazzling professional wonder of a day or of a year quietly fade into the most humdrum obscurity and dishonor. And even if there be an occasional example of such a character more or less permanently holding the clutched prize thus gained, it would still be true that the reckless self-assertion, the vanity, the disregard of others' rights, and the scorn of courtesy were really expenses and not helps, that a better success could have been achieved without their aid, and that success won by them finally poisons and palsies the heart of the winner with a secret shame and self-contempt that no laugh can conceal and that no office can make enviable. And these "successes" have to live in an atmosphere of suspicion and concealed dislike. They know that their assistants and subordinates secretly dissent from their methods, and have only disrespect for the motives of these their temporary masters. The masters have the service only so long as the self-interest of the servant is clearly assured. Their very friends and co-workers must be watched. Their patients are always "finding them out," and quietly slipping away. Nowhere is there love and loyalty and frank kindness. Nowhere is there enthusiasm for a great calling and the work of humanity's social progress; but instead there is a constant Machiavellian cunning to catch dupes, to avoid enemies, to guard against plots, and to push self to the front by politics and unscrupulous sharpness. Even the general public comes more and more to understand such men, although these make the great mistake of supposing that the public is deceived. There is a remorseless irony in the necessity that compels such to keep up the farce of pretended virtue, when everybody is pitying and smiling at the sorriness of the deception and the poverty of the disguise.

The lesson to be drawn from the life of the G.-T.-R. Doctor should be laid to heart, chiefly by the student and young physician with unformed character and unfixed life-motives. He is debating with himself as to whether he will imitate the "Success," or whether he will patiently and modestly and slowly win his way by means that will finally secure the respect of his own conscience and the honor and affection of his fellows. To such it should be urged that the method is of more importance than the attainment; that courtesy is more valuable than fame; and that power, money, and success may be bought at prices enormously above their true worth. In his heart the "Success" despises his imitators, and while seeking to injure, he still honors, those that will not assent to his methods. *Don't do it, young man; it doesn't pay.'—The American Lancet.*

Sulphate of Cinchonamine is a new antipyretic which is said to have some valuable properties. Le Gendre and Beaussenat have employed it in a number of cases of erysipelas, giving it by hypodermic injection in doses of four and one-half to nine grains. In some instances the effect upon the fever was superior to that obtained by any other antipyretic drug; but in others it was nil, and it was found necessary to resort to cold baths. In two cases the drug caused epileptiform convulsions, an effect which has also been observed in experiments with it upon animals.

ON LIPOMA OF THE TONGUE, MULTIPLE SYMMETRICAL LIPOMATA, AND THEIR ETIOLOGY.

BY JULIUS ROSENSTIRN, M.D.,

SAN FRANCISCO, CAL.

IN 1877, when Cohnheim's lectures on general pathology developed his new theory of the etiology of tumors, it seemed as if a sudden flash had lightened the darkness that had hitherto surrounded the origin of these growths. The opinion of this great scientist, that a defective embryonic structure was the cause of the appearance of tumors later in life, seemed to gain then the nearly undisputed recognizance of the pathological anatomists, until in this instance, also, a sifting criticism drew narrowing limits to its general adoption. Soon after the appearance of Cohnheim's book, observations, at first of malignant tumors only, were published which forcibly demonstrated the existence of other modes of origin than the one from stray embryonic germs. Later facts, gathered on an experimental basis, were added, which claimed a large share for an hereditary and acquired disposition in connection with accidental causes springing from the various pursuits in and modes of life. For the lipomatous tumors such predisposing influences are, in addition to traumatic causes, age. sex, and an inclination to excessive general fat formation, whether due to a certain manner of nutrition or to an individual predisposition.

Of the relation between nutrition and age to the growth of fat tissue, Virchow[1] says: "The influence of nutrition on the condition of the fat-tissue certainly deserves to be noted, and not only the influence of very fatty nutriments, but also of beer and strong alcoholic beverages." And further on: "A point in which lipoma greatly differs from other tumors, for instance enchondromata, is its comparatively rare appearance in early life and its distinctive feature of belonging to the middle and advanced age. This fact alone should suffice to prove the probability that the disposition is oftener acquired than congenital."

For the preponderance of lipomata in females I can quote, in addition to the general experience of most authors on this subject, a compilation of cases from an essay of Grosch, to whom I have yet to refer very extensively. His records, collected from various large hospitals and comprising six hundred and sixty-five cases of lipomata, while considering the rarer entrance of women into hospitals, show the relation of males to females in these instances to be like 1 to 2.

The traumatic causes may be divided into two groups: those having a slow or chronic effect appear in certain professionals, as millers, carriers, shoemakers, butchers, or others who are forced to expose some parts of their body to a continuous pressure. Cases of lipomata caused by acute trauma, as blows, knocks, etc., have been described by different observers, as Lücke, Volkmann, Koelliker, Zesas, and Grosch. Notwithstanding these indubitable facts, it would be wrong to deny to Cohnheim's views any part in the explanation of the origin of lipomata. In a recent essay of Jacobi[2] on congenital lipomata, this subject has been exhaustively dealt with. According to this excellent investigator, they appear in various parts of the body; but up to the date of his essay, only one case had been observed on the head, while the loins and gluteal regions are decidedly favored spots. He embodied in this essay the remarkable facts in favor of Cohnheim's theory, that the congenital lipoma is sometimes associated with other congenital anomalies, as nævi, cavernous angiomata, dermoidal cysts, fibromata, and congenital akromegalia.

In a most original treatise (published after the author's death, F. Grosch, by his teacher, Edward v. Wahl), F. Grosch[1] subjected the etiology of the lipomata to a very searching examination. From the books of the Dorpat clinic, and from hospital reports in different European countries, he collected seven hundred and sixteen cases of solitary lipomata, and examined their distribution over the different regions of the body. This investigation showed the surprising result that a decided preference existed for some parts of the body over others. While the entire scalp was only represented with 0.25 per cent., the forehead showed 1.50 per cent. The arms have 13.57 per cent., against only 6.86 per cent. of the thighs and 4.19 per cent. of the fatty gluteal region. Ahead of all ranges the back, with 21.54 per cent. without the shoulders, which claim 7.92 per cent., while the anterior surface of the trunk, the chest, only shows 6.18 per cent., and the abdomen only 2.37 per cent. In the numerical scale, according to extent of space, neck and shoulders show the greatest attraction for the growth of lipomata, then follows the posterior surface of the trunk until down to the nates, while the anterior half of the trunk shows a much smaller participation. The lower extremities are less favored than the upper ones; with both the density scale gradually decreases from above downward, to reach the lowest degree in the palms of the hands, and more so even on the soles of the feet. Not only the solitary lipomata, the multiple ones also, symmetrical or diffuse, show quite a similar order in their distribution over the body. Grosch relies chiefly on this fact in his opposition against Cohnheim's theory as the exclusive or principal explanation of the origin of lipomata. He asks the logical question, if fatty tumors really grow only from stray germs, why are they not distributed, at least approximatively, equally over the whole surface of the body? He then develops his views, based on the experience of a great many prominent authors, that the cause of many lipomata must be looked for in a disposition to general adiposis, either congenital or acquired; their localization, however, remains dependent upon the distribution of the glandular organs of the skin, the sebaceous glands.

In the absence of exact information as to the distribution of these glands, he estimates their density by that of the hairs, these two being nearly constant companions of each other.

According to Krause's and Unna's countings of the sweat-glands, they are distributed as follows: The skin of the back and of the extensor sides of all extremities shows a smaller number of sweat-glands than the skin of the breast, the abdomen, and the flexor sides of the extremities.

The parts mostly provided with glands are the soles of the feet, palms of the hands, flexor sides of the joints, axilla, the rima ani, the surroundings of the genitary organs, and the forehead. With the exception of the forehead, palms of the hands, soles of the feet, the distribution of the sebaceous glands is very much alike to the sweat-glands. The districts with plenty of glands, like

[1] Krankhafte Geschwulste, vol. i., page 392.
[2] Archives of Pediatrics, 1884, vol. i., No. 2.

[1] Studien über das Lipom. Deutsche Zeitschrift f. Chir., Bd. 26, p. 307.

the head, lower parts of the extremities, the flexor side of the joints, the inner surface of the extremities, mons veneris, perineum, and rima ani, rarely show lipomata; while those less favored with glands, as the back, shoulders, upper parts of the extremities, and of the extremities again, the lateral parts, are far more frequently affected. Grosch thinks that this arrangement of the glands shows a certain relation to the deposition of fat in the subcutaneous tissues. Where, through ample provision with sebaceous glands, a great deal of fat is secreted through the skin, there is not much panniculus adiposus; where, on the other hand, the glands are only sparingly scattered, the fat grows considerably. These physiological presumptions correspond with the distribution of the panniculus in lipomatous patients. On the back, neck, shoulders, arms, gluteal regions, and thighs, an enormous accumulation of fat takes place, while the scalp and the lower inner parts of the extremities change their forms but very little. Accordingly, the localization of lipomata agrees with that of the adipose tissue in obesity. The abdominal region occupies an exceptional position, it is very strongly developed in obese people, while lipomata occupy it very rarely.

Grosch tries to attribute this to the neighborhood of the digestive tract, which under ample nutrition, fairly inundates with fat the mesentery, the omentum, the subserous, and adjoining tissues, embracing finally the abdominal wall to such a degree that the glandular apparatus does not suffice to eliminate the superfluous fat.

He believes accordingly, that the obesity and lipomatosis represent pathological phenomena which are decidedly different from each other in their former expression, but perfectly identical in their character. He draws attention to the fact and illustrates it by a case of his records, that in persons with an abundant layer of subcutaneous fat the adipose tissue shows strongly developed lobuli, which are distinctly limited and freely movable. They are true lipomata, the same as those floating lipomata of the abdominal cavity.[1] A number of lipomata can therefore be considered simply as a part-symptom of general polysarcia. To understand the etiology of those lipomata that appear in slender individuals, he lays special stress on the frequent appearance of tumors symmetrically located, often evident in cases with multiple growths. The symmetrical distribution of skin-glands over both halves of the body, the secretion of which is regulated from common centres of glandular secretion (medulla oblongata and dorsal part of medulla spinalis), possibly indicates partial disturbances in these centres which find their expression in locally lessened secretion and consequent growth of lipomata. The growth of solitary lipomata could be explained by peripheral lesions that have caused trophoneurosis of the skin, or have directly injured the conductive tracts for secretion, and thus a number of lipomata would have to be considered as a product of a tropho-neuropathic lesion of the skin. Many points of these brilliant deductions are perhaps not sufficiently supported by facts. In the chapter on analogy of the distribution of lipomata and the increase of fat in obesitas universalis, a special stress is laid on the assurance that hands and feet, with their fingers and toes, are not changed by obesity.

I have made some measurements of the circumference of the hands and feet, as well as fingers and toes, of people suffering from obesitas universalis, and found considerable difference (twenty to forty per cent.) between these and well-nourished individuals of the same sex and height. It should not be forgotten that an increase of circumference of the body of ten to twenty per cent. makes a far greater impression than the same increase in the circumference of a finger. If one considers the large share of the osseous part in the volume of hands and feet, a part that remains the same in adiposity, I think a perfectly proportioned increase of these members can be demonstrated when compared with the others. These objections, however, are only of a less important character, and there remains enough of his thoughtful deductions to serve as a basis for his theory.

[1] Virchow: Krankhafte Geschwulste, p. 384.

The final result of these deductions would be: The localization of all lipomata is depending upon the relative quantity of glandular tissue and their function in various skin areas; the disposition for their growth being in inverse ratio to the supply of glands and their functional energy.

In the light of these views, I will report two cases that belong to the rarities of clinical surgery, and in their joint analysis may add a valuable contribution for the support of Grosch's theory.

My first case is a lipoma of the tongue, together with one of the left arm, which was followed later on by a third lipoma on an exactly symmetrical spot on the right arm. Lipomata of the tongue are very rare, and only a few cases are to be found in medical literature.

Paget [1] and Bastien [2] are, as far as I could ascertain, the first who called attention to them; a congenital lipoma of the tongue has been described in vol. I. of Virchow's Archiv.[3] In the year 1881, E. Mallon [4] treated the subject in his "Thèse des Lipomes de la Langue." He found in the literature eight cases, to which he adds one of his own observation. The lipoma was situated most frequently on the tip of the tongue, more rarely on the dorsum near the median line, and was only found at the base in cases of multiple development in the tongue. Characteristic symptoms are the slow growth, yellowish transparence through the much thinned expapillated mucous membrane, and pseudo-fluctuation. The tumor develops first in the substance of the tongue itself, and only later it becomes submucous and afterward pedunculated.

Apart from pure lipomata, fibro-myxo-osteo and congenital lipomata of a very complex nature have also been observed. Gosselin [5] described lipomata of the tongue in a man forty-eight years of age. The growth was very slow, the patient could ascertain the first traces twenty-five years ago. At the operation the tumor was as large as a walnut, pedunculated, and so completely isolated, that an origin from the muscles of the tongue was entirely out of question. The pedicle was tied with elastic ligature.

Cauchois [6] observed a case in a man fifty years of age. On each side of the margin of the tongue, but not reaching the apex, were a number of irregular protuberances of elastic consistency and covered with healthy mucous membrane with a yellowish tinge. He undertook the extirpation on one side, but did not entirely complete it. The patient soon died of phthisis that existed already at the time of the operation. Autopsy showed isolated lipomata at both margins of the tongue. He divides the lipomata of the tongue into three groups:

1st. Submucous, which are easily removed.

2d. Intermuscular, which follow the tracts of the connective tissue between the muscles. Extirpation difficult.

3d. Intra-muscular, mostly combined with those of the second group.

A successful separation of the tumors of the second and third groups seems very unlikely. E. Albert,[7] in Vienna, described a pedunculated fibro-lipoma. It was a little larger than a good-sized plum and was attached with a short pedicle, about as thick as a slate pencil, to the posterior part of the right margin of the tongue. These are all the cases I could find in the medical publications to which I have access. The case of Cauchois shows multiple lipomata in the tongue; no lipoma of tongue was associated with similar tumors on the body.

The first of my cases is the following:

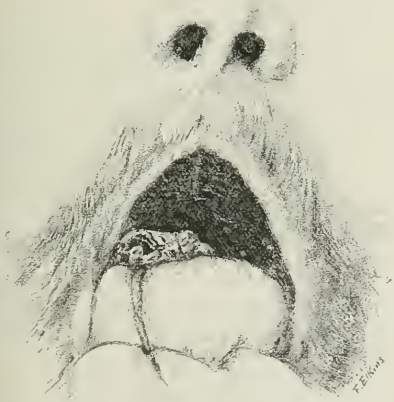
Case I.—A. S——, a young man, aged thirty-one, has, with the exception of scarlatina in childhood, always enjoyed excellent health. He observed in January, 1888, a swelling of the left submaxillary gland which disappeared after simple application of tincture of iodine. In August, 1888, he noticed a tickling sensation on the right side of his throat, to which he did not pay any particular attention at first. When the sensation gradually grew worse, he complained to several members of his family about the difficulty he had in swallowing solid substances. His sister looked into his mouth and discovered a growth upon his tongue. A physician who was consulted immediately diagnosed very probably a sarcoma (without microscopical examination), for his prognosis was a very bad one. The frightened patient came to me in December, 1888. He is rather slim but healthy looking, measures five feet ten inches in height, and weighs one hundred and forty pounds. In his family no case of tumors has been known to occur. Skin, rather dry. Perspiration has always been exceedingly profuse in both axillæ, so that even ordinary bodily exercise saturated his clothes with perspiration in the axillæ.

Examination of chest and abdomen shows normal conditions. On the right side of the base of the tongue, behind the papillæ circumvelatæ, close to the tonsilla linguæ, is a red, yellowish-tinged tumor, the size of a large English walnut. It is of soft consistency, pseudo-fluctuating, and reaches under the mucous membrane from



the anterior surface of the posterior plica glosso platima to the somewhat enlarged tonsil, forming with this an apparently continuous tumor. (See illustration above.) More careful investigation, however, allows the probe to enter from above, between the lateral part of the tumor and the tonsil, until it meets at the base of the tonsil the dislodged mucous membrane. Only when the tongue is pressed down forcibly and the patient gags, can the entire tumor be plainly seen. Ordinarily, the posterior part lodges in the lower part of the right half of the pharynx. The tumor is freely movable and nowhere adherent to the surrounding tissues. On the left arm, just below the shoulder, with the upper part joining the lower margin of the pectoralis major, lies a soft tumor the size of a walnut, freely movable under the skin. Patient observed it since about three months only. It grew quickly at first, and remained stationary for some weeks. The tumor of the tongue, as well as of the arm, never caused any pain, nor are they painful to the touch. A microscopical examination of a small piece of the tumor of the tongue shows it to be fatty tissue with the usual amount of connective partition-tissue.

With the assistance of Drs. Sherman and Kahn, on December 18, 1888, the tumor of the tongue was extirpated directly at its base with a galvano-caustic snare. Only cocaine anæsthesia was used during the operation. The closing of the snare was done very slowly, and there was actually no hemorrhage. There was no reaction and hardly any pain during the healing of the wound. The very evening of the operation he drank milk and ate oatmeal gruel, and the next day mush and soft-boiled eggs. After the sloughing off of the eschar, which was somewhat hastened by frequent gargling with solution of kali chlorici, I cauterized the remnants of the tumor around its base and also the bottom with crystals of chromic acid fused to the probe, boring into the different parts until I felt resistance. The growth seemed to me to be interstitial, as Cauchois says: a mixture of the inter- and intra-muscular form. A few weeks later the patient came to me and showed me a tumor that had formed on his arm until it had assumed the size of a small hen's egg. On January 13th it was extirpated, with the assistance of Dr. Kahn. It healed per primam, with the exception of a small space left by a catgut drainage in the lower angle.

At the end of March the patient showed me, on an exactly corresponding spot on the right arm, a soft tumor freely movable under the skin, about the size of a walnut. On the 26th of April, after having grown somewhat in the meantime, it was extirpated in the presence of Drs. Marshall and Kahn. The healing was perfect. After the skin had been severed both tumors could easily be taken out with blunt instruments. They were subjected to microscopical examination and showed the same structure as the lingual tumor, that of a lipoma transversed with a dense mass of connective-tissue fascicles. The patient came back again August, 1892, to consult me. No reappearance of tumor had taken place in any part of his body. Quick consumption, however, had set in with many bacilli in sputum. He was sent to Colorado, where he died in January of this year.

Creighton[1] first described in the dog, and later in man, the occurrence of a normal or tumefied species of skin-glands in the axillary region. They are situated under the skin, and a microscopical picture resembles fat-globules. They sometimes extend to the vicinity of the mammary glands. Their structure and functions class them as peculiar forms of sweat glands. The position of the tumors in my patient leads me to think there might be some anatomical relation between them and Creighton's sweat-glands. A careful microscopical examination showed, however, no trace of glandular tissue.

Case II.—D. R. B——, a full-blooded negro, aged fifty-three; weight, 225 pounds; height, 5 feet 7 inches; born in Maryland, and a cook by occupation, was forced seven years ago, through his malady, to leave his calling. Thenceforth the daily cleaning of business places furnished his means of livelihood. To his knowledge he was never forced to take to his bed from illness. Of his family the only one who lives in his memory is his mother, who never showed any growth on her body. She had a number of children, fifteen or sixteen, of whom he knows very little, but never heard of any similar affliction. He now has two sons, both being entirely healthy. As a young man he had a chancre, but no constitutional symptom.

In the year 1869, during a temporary residence in Alaska, he commenced to drink, and has since been conscientiously true to the habit. Seven years ago he first noticed the symptoms of his present complaint. The swellings first appeared and were noticed on the median line, extending along the nape of his neck; then they appeared on the inner side of his thighs, later on his arms, breasts, and legs, and on the outer edge of the lower jaw. The remaining tumors, the chronological sequence of which the patient was unable to give, are as follows: One on each side of the body back of the proc. mastoideus, on the right side the size of a hen's egg, on the left side that of a goose egg. One in the central line under the

[1] Charles Creighton, M.D.: Three Cases of Tumors arising from Skin Glands in the Dog, etc. Transactions of the Medico-Chirurgical Society, vol. lxv.

proc. ensiformis, in the regio epigastrica, the size of a hand. One on each side of the body, under the spina scapulæ over the teres major, about the size of a fist, on the left side larger than on the right. One on each side of the body in the lumbar region, a little larger than the one in the vicinity of the stomach, and the left one larger than the right. One on each side of the anterior inner surface of the thighs, extending from the upper boundary of the mons veneris to the lowest point of the scrotum. The surface measure taken longitudinally is on the right side 23 ctm., on the left 33 ctm.; the exact circumferences are as follows:

RIGHT.

Arm, 5 ctm. below the acromion, 53 ctm.
Arm, 5 ctm. above the apex of the olecranon, 42 ctm.
Forearm, 5 ctm. under the apex of the olecranon, 35 ctm.
Forearm, 7 ctm. below the apex of the olecranon, 35 ctm.
Wrist apparently normal, 18 ctm.
Circumference of hand around metacarpal phalangeal joints, 23 ctm.
Middle of first phalanx of index finger, 8½ ctm.
Middle of first phalanx of little finger, 7½ ctm.
Middle of first phalanx of thumb, 9 ctm.
Thigh, 16 ctm. below spin. ant. sup. ossis ilii, 77 ctm.
Middle of thigh, 59 ctm.
Middle of calf, 37 ctm.
Ankle, 27½ ctm.

LEFT.

Arm, 5 ctm. below the acromion, 49½ ctm.
Arm, 5½ ctm. above the apex of the olecranon, 47⅜ ctm.
Forearm, 5 ctm. under the apex of the olecranon, 35½ ctm.
Wrist apparently normal, 18 ctm.
Circumference of hand around metacarpal phalangeal joints, 21½ ctm.
Middle of first phalanx of index finger, 8 ctm.
Middle of first phalanx of little finger, 7 ctm.
Middle of first phalanx of thumb, 8⅝ ctm.
Thigh, 16 ctm. below spin. ant. sup. ossis ilii, 78½ ctm.
Middle of thigh, 56 ctm.
Middle of calf, 40 ctm.
Ankle, 31 ctm.

From the meatus auditor, extending on one side along the outer edge of lower jaw to the meatus on the other side, 40 ctm.
From the right corner of the mouth, across the lateral part of chin to the dividing line between head and neck, 14 ctm.
From the left corner of the mouth, across the lateral part of chin to the dividing line between head and neck, 15 ctm.

As his deformity gives him a certain degree of notoriety, he is perhaps rather proud of it. With one exception, these growths cause him no particular discomfort, and the only exception is the tumor in the acrobiculum cordis, which seems to press on the underlying organs and indirectly on the diaphragm, causing thereby difficulty of respiration. The patient at least attributes to this tumor the dyspnœa caused by even a slight effort. As lungs and heart are normal, his view may be correct.

If this difficulty increases he may perhaps consent to the extirpation of this troublesome tumor. At present, however, he is violently opposed to any sort of operation, being firmly set even against the excision of a small piece for microscopical analysis. I succeeded, however, to perform a series of experiments on him with regard to the Grosch theory, on the origin of these tumors. In order to obtain his permission I was unfortunately obliged to represent to him that these experiments would have a salient effect on the growths. I thought, if according to Grosch's theory, the growth and origin of these tumors had some relation to secretory disturbances of the sebaceous glands, or to their numerical decrease in certain areas of the skin, perhaps the anatomical association of the sebaceous and sweat glands would aid me to gain some confirmation, by an experimental demonstration of the absence or decrease of the sweat secretion in the tumefied parts.

By a series of subcutaneous pilocarpine injections I found that those parts of the skin covered with lipomata were conspicuously free, while the directly adjacent parts were covered with perspiration. Following are a few notes from my experiments:

June 30, 1893.—10.19 P.M.: Injection of 0.03 pilocarp. mur.; 10.21.30 P.M.: Salivation begins; 12.23.30 P.M.: Perspiration on back of head; 10.24.10 P.M.: Perspiration on forehead; 10.25 P.M.: Face perspires profusely, with the exception of those portions of the chin and cheeks occupied by the lipoma; 10.26 P.M.: Shoulders perspire freely. Nape of neck, seat of a large lipoma, is dry. 10.28 P.M.: Perspiration pretty nearly universal, but there is absence or quite a lessening of it on all places occupied by fatty growths.

June 23, 1893.—10.08 P.M.: Injection of 0.02 pilocarp. mur.; 10.17.15 P.M.: Salivation begins; 10.18.15 P.M.: Drops of sweat off the scalp; 10.20 P.M.: Perspiration over entire scalp; 10.20.15 P.M: Perspiration on forehead; 10.20.25 P.M.: Perspiration on ears and nose; 10.21.25 P.M.: Light perspiration on both shoulders. Nape of neck free from perspiration. 10.27 P.M.: Perspiration on hands and soles of feet. Ankles dry. 10.28 P.M.: Inner surface of wrist moist; 10.32 P.M.: Perspiration stops.

July 7, 1893.—9.45 P.M.: Injection of 0.015 pilocarp. mur.; 9.05.10 P.M.: Light salivation begins; 10.03 P.M.: Second injection of 0.015 pilocarp. mur., as no perspiration comes; 10.07.25 P.M.: Perspiration on temples; 10.07.45 P.M.: Perspiration on back of head and sides of head; 10.08.40 P.M.: Perspiration over whole head; 10.09.15 P.M.: Perspiration on both shoulders; 10.09.45 P.M.: Perspiration on breast; 10.10 P.M.: Perspiration on face and abdomen; 10.11 P.M.: Skin over tumor on neck dry; 10.12.30 P.M.: Thigh wet from perspiration. Tumors are dry. 10.15 P.M.: The whole back covered with perspiration except tumors in the lumbar region; 10.20. P.M.: Perspiration stops.

I took occasion to show this patient to the members of the San Francisco County Medical Society in the meeting of June 13th, and to demonstrate the results of a 0.02 pilocarpine injection in the following meeting of July 11th (see report of meeting in *Pacific Medical Journal*, July and August numbers). I am fully aware that these experiments only show an interesting fact. Although the anatomical associate location of the sweat and fat glands cannot be doubted, the equally close vicinity of the centres of secretory innervation and their physiological harmony can only be accepted as probable. These experiments, moreover, have only illustrated the destroyed or considerably decreased sweat-secretion of certain skin areas, but left it undecided if centrally or peripherically located causes were to blame for the disturbed function. The exaggerated knife-scare of the patient hitherto prevented an anatomical examination of the skin. I believe, however, that these investigations, as links of a chain later to be completed, are not without value.

If we try to analyze the two cases regarding their etiology, we arrive for the first one to about the following results: With the exception of the tongue, where the tumor is unilateral, the lipomata are arranged symmetrically. There also seems to exist a connection between the cessation of fat-storage in one part of the body and the consequent increase or neoformation in another. A supposed paucity of perspiration in those places where the symmetrical lipomata grew, could not be ascertained; the profuseness of perspiration in the axillary region may exist close to a dry spot, as demonstrated experimentally in the second case. With him the symmetrical distribution of the lipomata is classical; they are situated on their characteristic points of selection, and as a grand total he perhaps cannot be duplicated. Possibly his alcoholic excesses are partly responsible in causing these tumors, although his intemperance precedes their appearance by many years.

The chain of facts supporting the theory of Dr. Grosch's unfinished work shows some gaps yet. The distribution of the lipomata on fat people (especially in the first four cases of my additional list) does not always correspond to the distribution of glands and hairs. The cases, however, speak for a central cause; whether in the centres of the skin-glands only, remains to be seen. It would not be impossible to accept, as an auxiliary explanation, that the fat deposition, the general as well as the local

one, is regulated centrally with the aid of certain irritations arising from the resorption in the intestinal tract. This fat-formation may find its expression of morbid exaggeration in the growth of lipomata, as on the other hand local disappearance of fat occurs in certain atrophic changes.

A multiple growth of lipomata, accordingly, would signify a centrally-working irritation for a localized peripherical accumulation of fat, and in exactly as many centres regulating the involved parts as there are lipomata. If the irritations are symmetrical, we get symmetrically located lipomata; if not, there is irregular distribution. Should the objection be raised that a locally increased deposition of fat is no lipoma, we can point to the fat-polypi one finds in the abdominal cavity, the lipomata of the omentum, of the mesentery, of the kidney, and the enlarged appendices epiploicæ, to those forming in the skin as lipomatous skin-polypi, etc.[1]

I only wanted to mention here the possibility of such an explanatory attempt, as it seems to me to explain many things more perfectly. Theoretical speculations, however, are not the order of the day, and we must wait for further proof before their acceptance can be pressed.

LITERATURE.

The literature on multiple lipomata has been given by Grosch nearly completely, and I shall only add a few cases here which I found missing.

BACTERIOLOGICAL RESEARCHES INTO THE ETIOLOGY OF THE SO-CALLED CHRONIC RHEUMATIC JOINT INFLAMMATIONS.

By PROFESSOR MAX SCHÜLER, M.D.,

BERLIN, GERMANY.

I was unfortunately prevented from being present as a guest of the Pan-American Medical Congress at Washington, where I proposed placing before the American profession a report of some microscopical and experimental researches on the origin and etiology of the joint diseases due to chronic rheumatic ones, and to show there my microscopical, bacteriological, and pathological preparations, as well as some of the animals artificially affected with a similar or the same joint disease. Therefore I take the opportunity of presenting my views briefly in your well-known journal.

In a paper partly read before the twenty-first meeting of the Society of German Surgeons, 1892, and at full length published in the reports of this Congress, as well as in "Von Langenbeck's Archiv für klinische Chirurgie," Vol. 45, part 1, entitled "Chirurgische Mittheilungen über die chronisch rheumatischen Gelenkentzündungen," I explained the clinical and anatomical features of these joint diseases, based on the observation of one hundred and sixteen cases in my own practice. I confirmed and demonstrated that the swelling and some other external appearances of the joints are dependent on a characteristic chronic inflammation of the synovial membrane and of the synovial villous excrescences, which leads to an inflammatory growth or hyperplasia. I showed that light cases of this kind can become by degrees such very severe ones with an enormous accumulation of villous excrescences in the joint, which since Johannes Müller are called "Lipoma Arborescens," and make such immense knotty swellings and deformities of the joints, and cause such great deviations of the common position and of the natural use and function of the limbs, at times also such pains, that they often were erroneously believed to be a form of gout or of arthritis deformans. But they have nothing to do with gout or arthritis deformans, and also the name "lipoma arborescens" is not justified, as my close histological examinations exhibited the inflammatory origin of the excrescences.

[1] Virchow: Krkhfte Geschw., i., p. 379, etc.

Moreover, I found in the inflamed tissues of the synovial membrane and of the synovial villous excrescences, small microbes, short and clumsy, the central portions of which are lowly notched or grooved bacilli, with shining granules in the poles, which can be tinged by aniline colors. I found them also in freshly excised portions of joints of living patients, from which I had excised the whole synovial membrane thickly covered by hyperplastic villous excrescences ("arthrectomia synovialis"). I took, by means of a small aseptic puncture with sterilized instruments, out of a diseased joint which was filled with villous excrescences, a drop of synovial fluid or fluid of the tissues, and put this in a tube filled with stiff bouillon-peptone-gelatine. I was fortunate enough on the first trial to see the development of a culture of microbes, which represented in every point the same form and shape of the bacilli found in the inflamed tissues and in the villous excrescences of the joints.

This result induced me to repeat such puncture-inoculations in other more or less diseased joints and on other patients, in meat-juice, gelatine, bouillon, peptone-gelatine, etc.; and in every case the same short bacilli were found.

The puncture-inoculations I made with a puncture-needle of my own invention, a hollow needle with a stiletto exactly fitting the canal, and both obliquely bevelled. This and all other instruments before use were always sterilized by steam in my sterilizer, the trustworthiness of which I have tested on many occasions by bacteriological experiments.

Subsequently, I made experiments on animals with these cultures of bacilli. Injections in the joints of pigeons had no result, as possibly the quantities taken for the injection were too small. In rabbits small injections in a knee-joint caused a swelling of some weeks' duration. But larger injections of 0.5 to 1 gramme culture-fluid produced an increasing and enduring inflammation of the joint, with a large swelling and a large expansion of the capsule. The animal's limb lost in the beginning a little flesh, but recovered afterward, while the swelling of the joint remained. I killed these animals after two months, and found in the diseased joint no pus, only a little synovia containing few cells, fragments of cells, and numerous short bacilli of the same shape as in the cultures. The synovial membrane was inflamed and covered with many red or brownish villous excrescences ramified as the branches of a tree (dendritic), others more solid ones, leaf-shaped or digitiform, extended with club-shaped ends. They have a similar structure as the inflamed and hyperplastic villous excrescences found in the joints of men, and represent in miniature also a quite similar picture as the latter. Puncture-inoculations of these diseased joints of the rabbits, taken out shortly before the death, showed the same short bacilli cultures. I used these for the experiments on rabbits, with the same results. Also in a case where I injected the culture fluid through an aseptically made perforation of the lower epiphysis of the femur. This caused inflammation of the knee-joint with the same characteristic signs which I have described.

These researches and experiments demonstrate, or make it at least in a high degree probable, that the chronic inflammations of the joints with hyperplastic villous excres-

cences which we till now believed to be rheumatic, are produced by the influence of the bacilli first discovered by myself in the tissues, and are cultivated by puncture-cultures out of the inflamed joints.

By other experiments I demonstrated that these bacilli never cause suppuration. Small injections under the skin show merely a passing inflammation, swelling, and induration; larger injections kill the animals after twenty-four hours with signs of a septicæmia.

In the situation of the injection was an œdema, in which could be found the same bacilli. These could be cultivated out of the œdematous fluid, as well as in some cases out of the blood of the right heart, which abounded with bacilli.

I pass over other experiments, by which I endeavored to discover the possible ways of invasion of these bacilli in men. Perhaps I shall be able, on a future occasion, to give an account of my researches regarding this important question.

Not long since I had an opportunity of making puncture-inoculations out of the joints of one patient with the rather rare third form of "chronic rheumatism" of the joints, which we call "arthritis rheumatica chronica ankylopoctate," as it, according to my observations, certainly begins also with a chronic inflammation of the synovial membrane and with the growing out of villous excrescences, but later on leads always to a shrivelling of the capsule, and at last to anchylosis by partly fibrous, partly cartilaginous, partly osseous union of the joint. I have found, and at several times (loc. cit., and yet in my book, "Pathology and Therapy of the Inflammation of the Joints," Vienna and Leipsic, 1885) stated, that also on these coalescing joints mostly are left some parts of the synovial capsule with villous excrescences, remaining not united. These remaining parts of the capsule form a small pocket, or a hard knot, which give the appearance of a bony swelling or protuberance, but which is, according to my investigations, nothing more than a small expanded part of the capsule, with compressed and tightly-enclosed hard villous excrescences. They not infrequently cause swelling and pain, even after the joints have become quite stiff. The patient which I mentioned I saw for the first time four years before. Since then he has experienced a varied treatment in several clinics and hospitals, without benefit. He was a man thirty-five years of age, but looks like an old man quite contracted, and is not able to stand upright, as his hips and knee-joints are in an angular position. His left shoulder-joint is quite immovable, also some of his digital joints; the other joints of the arms are less stiff. The right hip-joint is in nearly right angular position and fixed. The right knee-joint is also contracted, but in a small degree movable; the other joints of the lower limbs are less affected. Some of the joints of the vertebral column seem also to be stiff. In the right anchylosized hip-joint, near the upper, outer, or posterior part of the acetabulum or of the joint, I could feel a very small protuberance, which was painful even independently of pressure. This condition I am inclined to take as a small remaining accumulation of villous excrescences compressed in a resting part of the coalescing capsule.

In the right knee-joint I could feel quite distinctly some hard villous excrescences in the synovial capsule near the outer border of the patella, which was also tender on pressure, and gave rise at times to pain and swelling. Out of these two places, on the hip-joint and knee-joint, I made, on September 1st, puncture-inoculations, with all measures of precaution in tubes and plates, with bouillon peptone gelatine, and in tubes with bouillon peptone agar-agar; one also in a small drop of bouillon peptone gelatine on a thin plate of glass, for a continued microscropical observation in a small sterilized glass case made for this purpose. To-day, five days later, I can say that also in these cultures are developed short bacilli of the same shape as described above. It seems, therefore, also, from this point of view, that I am justified in adding these joint diseases; though in the latter, owing to their inclination for anchylosis perhaps besides, yet other efficients may be active, what by further investigation, I hope, will be disclosed.

According to my researches, I must doubt if the acute rheumatism of the joints has such a near relation to these inflammations of the joints which we called till now "chronic rheumatic" ones as is believed in general. Then, in acute rheumatism of the joints are found usually only suppuration-producing cocci, mostly the staphylococcus or streptococcus; in one case, as I know, also pneumococcus; in all my cases of the so-called "chronic rheumatic" joint inflammations which I have till now by bacteriological means examined, I found always my short bacilli which never produced suppuration, but made in the joints of rabbits a most characteristic inflammation with villous excrescences similar to that which we find in the so-called chronic rheumatic inflammations of the joints of men. This induces me to believe that they represent an especial form of inflammation of joints caused by my bacilli, for which a preceding acute rheumatism of the joints may, perhaps, only prepare the place. I think that the short bacilli easily enter the joints which have been the subjects of acute rheumatism. I am inclined to believe that a similar influence can be derived from some other foregoing inflammations. As, according to my clinical researches, many patients with so called chronic rheumatic inflammations of the joints are affected by chronic catarrhs of the genito-urinary, nasal, and respiratory organs, I have the opinion that, perhaps, these will be found the source of the short bacilli. Or they may be found outside of the living body, and only by some especial influence enter the natural openings of the human body. These and other questions may find an answer after further investigation. Further study must also be applied to discover means and remedies for the care and healing of these dreadful diseases. We cannot be content and satisfied to know what produces these diseases; we must know how to prevent them, and if it is possible, how to free the diseased patient from this invasion. Let us hope that we may reach that which I call the fruit of medical knowledge. Over the biological properties of the bacilli found by myself, I will, with restriction, make the following statements: The bacilli yet described above are stained most easily by carbo-fuchsin, but they are very easily also discolored by acids, etc., often more than desirable. The protoplasm of the bacilli is mostly condensed in two parts, which are of a roundish, oval, or cylindrical shape, and lie closely, or are separated by a very small clearer part. The bacilli measure, according to measures with an ocular micrometer of a great Seibert microscope, lengthwise 2.24 to 2.76 μ, mostly 2.62 μ; in the breadth, 0.75 to 0.95 μ, exceptionally 1.02 μ. They are not always straight, but sometimes a little curved or angular. They are very easy to distinguish from tubercle-bacilli, as well by their shape as by the coloring reactions and by the mode of development in cultures.

According to the observations which I made till now with numerous cultures of the above-described short bacilli, I can say that they grow good in a temperature which must be a little higher than the usual temperature of our rooms, I will say 25° C. They grow, as it seems, better in a somewhat higher temperature; but I have not yet determined the "maximum." A preliminary condition for the growing is that the cultures are kept quite dark. Exposed to the sun or to the glaring daylight, they do not grow at all, or show only a very poor, scarcely visible vegetation, even when later again kept in the dark. After puncture-cultures in gelatine there appeared in the next two, three, or six days very small, separated white knobs or grains along the stitch in the gelatine; afterward a white-veiled swelling or soaking which unites the separated little grains and then liquefies the gelatine and last becomes more opaque white in a well-marked extension from above down. Or it begins the swelling and white clearing up in the gelatine along the extension of the puncture very soon, the gelatine liquefies in the same extension, then becomes from above down opaque white.

On sterilized glass plates begins the culture from small white or white-grayish spots, also here the gelatine becomes liquefied in the further stations of the growing. In bouillon, peptone-agar-agar, the cultures make white-grayish spots or little membranes, the same on cooked potato or carrot slices. On potatoes the cultures taken out of the joints of rabbits seemed to grow better than the cultures taken from the joints of men, some of which failed on potatoes.

September 5, 1893.

A CASE OF ACROMEGALY COMBINED WITH SYRINGOMYELIA.

By FREDERICK PETERSON, M.D.,

NEW YORK.

CHIEF OF CLINIC, NERVOUS DEPARTMENT, VANDERBILT CLINIC, COLLEGE OF PHYSICIANS AND SURGEONS.

THE following history of a case which has been under treatment by Professor Starr and myself at the Vanderbilt Clinic for some months past will, I am sure, be of interest in that two rather rare disorders are combined in one and the same person.

Annie R——, single, aged thirty five, came to the clinic some three or four months ago complaining of a number of symptoms, weakness, anæsthesia, and the like, the first onset of which she claimed to be not over a year ago. She is five feet five and one-half inches in height and weighs one hundred and seventy-two pounds. The only particular illness she had ever had up to that time was some lameness at the hip joint, dating from a fall at the age of seventeen years. There is no specific history in the case.

Upon examination she presents the following complicated syndrome: Her face is very large and puffy; the lower jaw is particularly large; the hands are very large and stumpy (battledore-shaped). One photograph shows the face and hands and the other exhibits the hands alone, her sister's normal hand at one side having been taken at the same time for purposes of contrast. I am indebted to Dr. Power for these photographs. The patient does not know how long she has observed this increase in size, but that her hands, face, and feet have been appreciably enlarging for a year or more both she and her sister are aware. In the photographs it will further be noted that upon the left hand are numerous abrasions and small ulcers that have no disposition to heal. The nails are short, curved, small, brittle, and cracked.

FIG. 2.

As to motor symptoms, her fingers are somewhat flexed, the hands tending to take the *main en griffe* position. The possible movements of the fingers are very slow. The muscles of the shoulders are weakened, so that she is unable to lift them to her head. There is weakness of some of the spinal muscles, so that she has a lateral curvature. The thigh muscles are stiff, particularly in the left extremity, so that she walks with difficulty, cannot step upon cars or walk up-stairs. The left knee

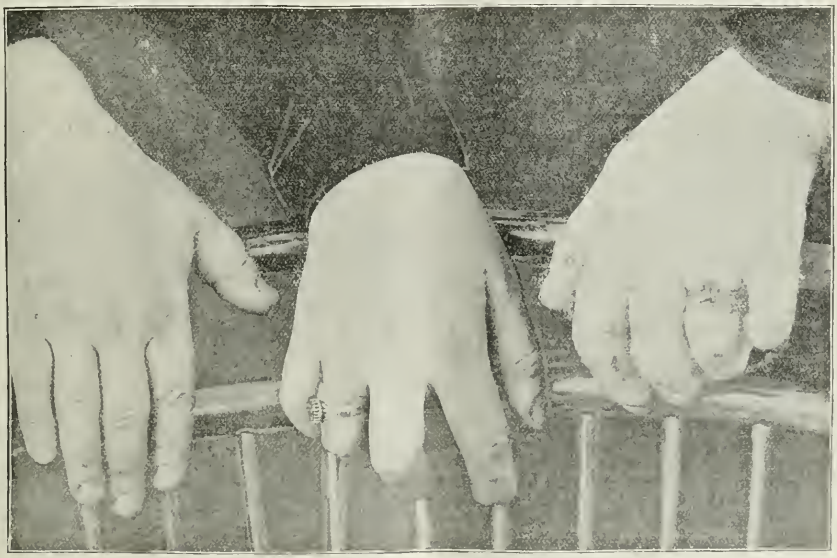

FIG. 1.

feels weak and is inclined to give way. She can stand on her heels and toes, showing that the flexors and extensors of the feet are normal. In such muscles as could be examined readily (ulnar distributions) there was partial Dg. R. The eyelids of both eyes droop a little. It is not a marked ptosis. There is rotary nystagmus in both eyes.

As regards the reflexes, there is myosis with sluggish pupils (the right reacting almost imperceptibly, the left not at all). There is a marked jaw-jerk; there are no wrist-jerks, elbow jerks, or tricep-jerks on either side; the knee jerk on the left side is notably diminished, but marked on the right side. There is no ankle clonus. She has difficulty in retaining her urine and frequently wets herself. Her breathing is shallow and she has slight difficulty in swallowing.

The sensory symptoms are a complete loss of pain and temperature sense in the left hand, forearm, and arm, extending upward on the shoulder and up the left side of neck. There is very slight tactile anæsthesia in the left hand and fingers. A very remarkable phenomenon is hypercryalgesia in the whole of the left leg extending upward some distance above the thigh and hip. Touch, thermal sense, and pain sense are unimpaired, but cold, moderate or great, produces a pain which she compares to burning. Though blindfolded and though several test-tubes with warm and cold water were employed, she would invariably jerk her leg away when touched by a cold one, exclaiming "It is hot," or "It burns." The drawing (Fig. 3) exhibits the areas of lost pain and temperature sense and of hypercryalgesia. There was no disorder of the visual fields.

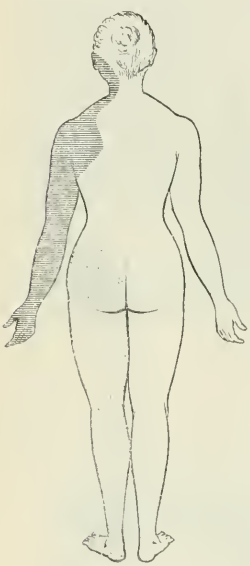

Fig. 3.

I have rather carefully examined the literature of the subject and have not found any cases similar to this in which both syringomyelia and acromegaly were present in the same person.

Since the above was written the patient died, August 4, 1893, with symptoms showing disturbance and failure of the nervous mechanism governing the cardiac and respiratory movements. Unfortunately an autopsy was resolutely prohibited.

Law and Medicine.—We have directed attention to the fact that railroad doctors are the poorest paid of all railroad employés, while railroad lawyers are the best paid. Farther, these latter become in a professional way so familiar with changes in railroad affairs that they are able to purchase or sell railroad securities to their own certain profit. In a well-known accident-insurance company a lawyer receives a salary of ten thousand dollars a year for about an hour's work daily; while a doctor, better educated and quite as able, who gives more than half his time in serving this same company, gets one thousand dollars per year. Comment is unnecessary. Of course the difficulty lies in the fact that the company wants this lawyer above all others, and pays him accordingly, while it would take anyone of dozens of doctors, should the one holding the place choose to resign it.—*American Lancet.*

THE TREATMENT OF BONE CAVITIES BY FILLING WITH COPPER AMALGAM.[1]

By OSCAR J. MAYER, M.D.,

SAN FRANCISCO, CAL.,

LATE ASSISTANT ON THE SURGICAL STAFF, MOABIT HOSPITAL, BERLIN.

The short time allotted to me prevents a review of all the work that has been done in regard to healing bone cavities. I shall only call your attention to some experiments I have made in the Moabit Hospital, in Berlin, during my time of service on the surgical staff, with a view of obliterating bone cavities, by means of plugging the cavity with inorganic material, following in the main the manner in which dentists fill carious teeth.

After attending a lecture of Professor W. D. Miller, delivered before the Association of American Physicians, in Berlin, where the pathological conditions of carious teeth were demonstrated, and the properties and antiseptic actions of some fillings explained, it occurred to me that some of these metals could be used in bone filling in place of other materials I had experimentally tried.

That foreign bodies can become encapsulated within soft tissues, as well as bone and even vital organs, is an established fact, which we often witness in gunshot wounds when the bullet is allowed to remain, although we do not know the exact process under which encapsulation takes place.

Although the conditions upon which the permanent encapsulation of fillings into bone depends are by no means so simple as in the case of carious teeth, the investigations and experience of the dental profession must, of course, form the basis of our experiments.

Above all, it was clear that the material used for fillings must be not only aseptic, but actively antiseptic, since it is certainly out of the question so to disinfect at one sitting the cavities which remain in the bones after chronic osteomyelitis or tuberculosis that all the bacteria in them are destroyed. If the filling is to become encapsulated it must, by virtue of its antiseptic properties, act upon the colonies of micro-organisms which may still be present, and thus destroy the exciting causes of the inflammation. Furthermore, such fillings must consist of a material which is light, non-poisonous, and hardens rapidly.

I am encouraged to make the present demonstration because of the interest a former presentation aroused at the Twelfth Congress of German Surgeons, and because I am desirous that the investigations so far made may be tested by others, and perhaps brought nearer to completion. For, although the question whether such fillings can heal within bones will soon be definitely answered, it will require years of observation to ascertain whether this method of bone-filling is to be regarded as an enrichment of surgical procedures.

Experiments were made with various metallic mixtures of as low a melting-point as possible, among others with the alloy of Wickersheimer, used for metallic corrosions of bones, which melts at 55° R. (156° F.), and the alloy of Lipp, which melts at 63° R. (174° F). But it soon became evident that these mixtures could not be of service, as they solidified in the funnel, and even if no funnel is used, the mixture does not flow properly if poured into a cavity which is below the above-mentioned temperatures. Attempts were made to transform aluminium into a soft mass, but as yet without success. With mercury, aluminium forms a spongy, porous mass, such as has been noticed when instruments of that metal have been put into a solution of bichloride.

Copper amalgam was made into a dough-like mass, in the manner customary in dental practice, by heating it in a spoon over an alcohol flame and rubbing it to a pillular consistency in a mortar. The cavity was either completely filled with the mass, or only coated with it, and a lighter filling material, a cement, gutta-percha, etc., used

[1] Read before the Surgical Section of the Pan-American Medical Congress Meeting, in Washington, D. C., September 5–8, 1893.

to fill out the defect. Plaster of Paris[1] (after Trendelenburg) at first was not used, because it is more porous and heavier than the above mentioned substances, and not so easy to manage; it also hardens more slowly, and is more liable to soil the surface of the wound. On account of the well-known instability of carbolic acid, it is not to be supposed that plaster-of-Paris fillings, made up with a five per cent. solution of carbolic acid, instead of water, will have any lasting antiseptic effect on the surrounding tissue. In one experiment, as we shall see further on, I used plaster of Paris after the cavity was coated with cotton amalgam, but as will be observed a great deal of shrinking took place.

Of cements the Harvard cement of Dr. Richter is particularly worthy of mention. I had made for my use a quantity of the lighter white sort of this cement, which shows the fewest pores. It also requires a much shorter time for hardening than any other cement, and shows no shrinking after hardening. On account of the expense of the latter I have set to work and experimented with a number of different cements and putties, and found that one of the most reliable cements, and at the same time very inexpensive, could be obtained in the oxychloride of zinc. I used this in my later experiments in connection with the copper amalgam. Its preparation is as follows: Zinc chloride, 4 parts; aqua dest., 5 parts; glycerine, 3 parts. Of this solution 10 c.c. is intimately mixed on a slab, by means of spatulas, with 10 gm. of oxide of zinc. It will remain in a pasty condition for about four to five minutes and then set, and show, upon being split with a hammer and chisel, none or very fine pores. Use was also made of Abbey's non cohesive goldfoil, the antiseptic effect of which had already been shown by Miller.

On account of the troublesome technique to properly apply copper amalgam, the substance which shows the most marked antiseptic effect on plate cultures of bacteria, I made use, in some experiments on animals, of coarse filings instead of the dough-like mass. The cavities were coated with this, and then filled out with cement, guttapercha, etc. We shall see, after describing the post-mortem condition of the bones that underwent filling, which is to be preferred.

The property of copper amalgam to check the development of various sorts of pathogenic and non-pathogenic bacteria has already been shown by Miller,[2] even in the case of fillings of this metal, which had been carried for years in the teeth. This has since been confirmed by Behring,[3] in his article on the means and methods of disinfection, and I have been able to show a direct antiseptic effect by the death of bacteria in plate cultures. I prepared, in the usual way, plate-cultures on agar agar of bacteria (staphylococcus aureus, staphylococcus albus, etc.), and after the colonies were fully grown placed a copper amalgam filling on the plate. Before putting in the fillings inoculations were made from the plates on agar tubes, and after twenty four hours other inoculations were made from colonies within a space of 1 to 2 ctm. from the edges of the fillings. In spite of many attempts, nothing ever grew except in the tubes inoculated before the fillings were put on the plate.[4]

It is worthy of note that the greenish discoloration appears much sooner and more markedly, and spreads over a larger space, if the metal is put on a plate on which the cultures are already grown than if it is put on immediately after the preparation of the plate. In the latter only a narrow green ring is formed around the filling; perhaps the more extensive discoloration is due to the chemical changes produced by the bacteria. Copper amalgam of various manufactures were used, and at one time it seemed that some possessed more marked antiseptic properties than others, but this was a result obtained during the time my incubator was out of order, and shows that if the plates are exposed to ordinary room-temperature the free space surrounding the copper amalgam will be much larger than when the plate-cultures are at once transferred to the incubator that registers 37° C.

The animal tests were made on dogs, some of which were operated on at one, others at two sittings. In order to get the filling closely into the bone defect it is desirable to have the cavity as dry as possible. In this case we are confronted with considerable difficulties with which the dentist does not have to combat, for we have to deal with a tissue richly supplied with blood, while the dentist has only to excavate the tooth, dry it with the hot air blast, and separate it from the mouth with rubber sheeting, in order to obtain a perfectly dry surface. such as we cannot obtain even with the tampon and the Esmarch constrictor. I have made use of the hot-air blast, and after considerable modifications I had constructed a hot-air blast by which a steady stream of hot air of 70° to 80° C. is obtained. It consists of a spiral platina loop, 20 ctm. long, which is lighted by an accumulator supplied with forty cells. It works very much on the style of a Paquelin thermo-cautery, a continuous supply of air being driven through the platina loop by a double blast. Before drying out the cavity with this I swab with alcohol and ether in order to facilitate the drying. Pressing in the filling will cause a slight capillary hemorrhage, not enough, however, to cause any disturbance.

Experiment I.—Bitch, aged six months. In morphine narcosis the upper epiphysis of the left tibia was chiselled open, the periosteum being also taken away and the medullary portion gouged out with a sharp spoon. The hemorrhage was checked by tampons, swabbing with alcohol and ether, and use of the hot-air blast, and the cavity was coated with prepared copper amalgam. During the filling a little blood had to be occasionally wiped out. The hollow of the filling itself was not filled out. Edges of wound closed with catgut sutures and a plaster-of-Paris bandage applied. The next day the bandage was found gnawed off and the stitches torn open. Another bandage was applied, but as this also was torn off and the wound began to secrete, no further attempt at bandaging was made. By the third day after operation the animal used the operated leg for standing and walking, and jumped into his stall without difficulty. The wound closed completely in eighteen days. On the twelfth day the depression in the filling was still visible through a little opening. Forty-four days after the operation the animal was killed. Wound of incision completely cicatrized and of a reddish appearance, plainly recognizable. Inner side of tibia, where it was chiselled open, shows marked thickening; no fistula present. On sawing the bone through longitudinally it appears that the filling has been made smaller by the formation of new parosteal bone-tissue, the newly formed bone-tissue having pressed upon it until the hollow which was in the filling has entirely disappeared. Only a slight crescent-shaped form shows that the filling originally filled around bone-defect, or rather covered it as a thin coating, leaving the middle of the cavity entirely empty. The surface of the section of bone in the neighborhood of the filling is somewhat darkened and discolored by the sawdust produced by sawing through the copper amalgam.

Experiment II.—Bitch, six months old. In morphine narcosis the same operation was performed as in the former experiment, except that a filling of the Harvard cement of Dr. Richter was used instead of copper amalgam. Progress of the healing about the same; after fifteen days the outer wound is entirely closed. Animal killed in forty-four days. The tibia shows marked thickening over the site of the filling. No fistula. On sawing through, the filling is seen to be completely healed in. In this case also the sawed surface in the neighborhood of the filling shows some yellowish discoloration, due to the sawdust from the cement.

[2] Mikroorganismen der Mundhöhle, 2. Aufl., 1893, p. 277.
[3] Desinfection, Desinfectionsmittel, und Desinfectionsmethoden. Zeitsch. f. Hygiene, Bd. ix.
[4] Since the above was in print I have learned from Professor Miller that he has also confirmed the above results by experiments on the pulp of living teeth.

Experiment III.—Dog, eight months old, operated on in two sittings. In the first sitting the bone was chiselled open in morphine narcosis, the medullary portion removed with a sharp spoon and a tampon of sterilized gauze inserted. Operation the following day, without narcosis. Tampon removed, the cavity lined with a coating of softened copper amalgam and then filled with Richter's Harvard cement. Soft parts sutured with catgut and bandaged. Bandage several times renewed, but always gnawed off; progress of the healing slower than in the preceding cases. In this case there existed a deep fistula, through which the filling can be felt with a sound. The filling, however, seems to be firmly healed in. The fistula closes twenty-eight days after the operation, and the wound heals in the course of the next week. The animal is killed forty-three days after the insertion of the filling. In the soft parts the cicatrized fistula may be easily distinguished from the rest of the scar tissue by its more reddish color. The tibia being freed from the soft parts, a not yet calcified spot may be recognized as the former bone fistula; it is, however, completely covered with thick granulations, which is connected on the inside with the bone tissue. It is much more difficult to saw through the bone in the region of the filling than in the preceding cases. After the bone is sawed through it is seen that a small portion of the gauze had been left in the cavity. The filling is considerably broken up, which I explain as the effect of the pulling of the saw teeth, which were clogged with shreds of gauze on the filling, which was not firm enough to stand such violent treatment. In this case also the neighborhood of the filling is discolored by the amalgam.

The next experiments were carried on to determine how older animals would stand the operation of bone-filling, and whether they would become perfectly encapsulated, as also to find out which was the better technique—filling with softened copper amalgam or that with coarse filings of the metal.

Experiment IV.—Dog, eight years of age, sixteen pounds. In morphine narcosis the tibia is chiselled open, as in the previous experiments. Instead of softened copper amalgam, the coarse filings are used, with Harvard cement. After sixty days the animal is killed. The defect in the bone over the site of the filling is partly closed with new bony tissue, partly with granulations. A fine sound cannot be passed through anywhere. After sawing the bone open, longitudinally, it is seen that the filling is somewhat torn. This seems to show that the filling does not fit as tight when the filings are used instead of the softened metal, as we witness this tearing of the filling in every case where the former was used.

Five more experiments were made with older animals, and while all the fillings remained in and the wound became smaller, not enough time elapsed between the date of operation and the day the animals were killed to be definite as to the time required in old dogs to become perfectly encapsulated.

So much in regard to the experiments thus far made. In addition to the successful experiments just reported, Professor Sonnenburg has made use of the method of bone filling, proposed by me, on two patients suffering with chronic osteomyelitis, and while they were unsuccessful they still offer a great deal of interest, and show that, if properly made, a filling can become encapsulated. The operations were made at a time when the technique was anything but well tried. Again, it shows that no one should attempt bone filling in the above manner with copper amalgam until after he has practised it either on the dead or lower animals, and acquainted himself thoroughly with the different manipulations. *There is a decided difference between simply filling a hole in a bone and the proper adjustment of a filling to a bone cavity.*

One filling came out after two months; it had been tightly seated for about fourteen days, when it became loosened and was gradually expelled. Right behind the filling was found a sequester, about one-fourth of an inch broad and one inch long, which evidently had been overlooked at the time of operation. The filling itself, as will be observed, is rather irregular; instead of being evenly covered with copper amalgam, the latter has been crowded on to one position. It will be seen that on one side newly formed bone-tissue is closely attached to the metal and cement. As these cases will be reported by Professor Sonnenburg I shall not loose time in dwelling upon them here. One case of bone filling for chronic osteomyelitis, of ten years' standing, in which I have inserted a filling weighing approximately 120 gm. (4 oz.), has been left to me by Dr. Rieger, Director of the Surgical Department of the All Saints' Hospital, in Breslau. The results of this case will be published by the surgeon in charge as soon as definitely known.

No one is more conscious of the incompleteness of this work than myself, and in giving it I entertain hopes that those of you, gentlemen, who have material at their disposal will take up this subject, and reveal whatever merits or demerits it may possess and give the results whatever publicity they deserve.

In addition, I have tried copper amalgam in the treatment of chronic gonorrhœa by application of sounds covered with that metal.

Experiments are also in progress to see whether O'Dwyer's intubation tubes, covered with copper amalgam, have any direct action upon the primary focus in diphtheria, and are capable of preventing the downward spread of this disease.

TRAUMATIC UTERINE HEMORRHAGE—SOME NEW ADAPTATIONS.

By WALTER S. WELLS, M.D.,

NEW YORK.

On July 20th I was called to attend Mrs. M. G——, aged about twenty-eight, pluripara, who was flooding copiously, and vomiting. After meeting the exigencies named, I learned that about seven weeks before the date above named this woman had a severe accident, causing abortion. While hanging out clothing upon a line running upon pulleys, one of which was attached near the window out of which she was leaning, and as she was grasping this end of the line with one hand while adjusting articles of clothing with the other hand, the near pulley broke, and the whole weight of the clothes line with its bearings suddenly precipitated her against the stone base of the window, upon which her abdomen collided with sufficient force to rupture the intra-uterine envelope of a three months' fœtus. She clung to the rope until her screams brought neighbors to her assistance, and in due time, after removal to bed, the remaining contents of the uterus followed the first gush of amniotic fluid and blood.

Notwithstanding the sanguinary spectacle and the serious nature of its cause, these well-meaning neighbors with stolid assurance, proceeded to administer to the situation without medical aid, leaving nature to dispose of such remnants of secundines as might have remained, and to institute measures to obviate subinvolution.

No obstetric binder had been applied at any time since the accident up to the time of my call, nor had the patient given herself the customary rest in bed, but as soon as she could, got up and "dragged herself around," to use her expression, "swaddled in towels" to absorb the blood flowing incessantly from the uterus.

She even went up and down stairs and out upon the streets in this condition for seven weeks, including the hottest weather we have had in this city for years. By this time, as might be expected, the woman was in a condition of extreme exhaustion; but her staying powers were to be yet further tested, and this happened from some overexertion in her domestic avocations. This last accession in degree of the hemorrhage I found accompanied by marked disturbances of a sympathetic character—vomiting, diarrhœa, and præcordial pains.

The most urgent indication was to arrest the fur-

ther loss of blood, and this was promptly accomplished by packing the entire vaginal tract with dry Tannin, using a hollow cylinder about eight inches in length and fully one inch in the diameter of its bore, with a piston working loosely so as to allow the easy pressing out of the astringent powder upon and around the os uteri. Two charges of the cylinder filled with dry Tannin completely packed the vaginal space.

An obstetric binder was extemporized by folded towels and a strip of muslin, and was being fastened to maintain pressure directly over the site of the uterus, simultaneously, by the aid of an assistant, while the Tannin tampon was being placed.

Long experience of the constringing effects of Tannin thus applied in cases of flooding was here confirmed, for the flow stopped and did not return, notwithstanding the recurring vomiting. This persistent vomiting became the next urgent difficulty to overcome.

As usual after great hemorrhages, from whatever source, the patient complained of intense thirst, but it had been impossible to alleviate this by reason of the rejection by the stomach of all fluids, warm or cold, that had been tried.

I sent for a siphon of Kumysgen, and prepared it according to the directions. The patient drank with avidity the foaming preparation, and we watched with suspense the result. For a few seconds the stomach rebelled and efforts were made to dislodge, but the action of the carbonic acid gas generated during the solution of the Kumysgen was very rapid upon the mucous membranes of this organ, and no more vomiting occurred. The diarrhœa also ceased as the enteric tissues became engaged with a preparation they could assimilate. In short, for at least a week the patient took no other preparation, food or drink, nothing but Kumysgen.

I did not dare to make any experiments in such a desperate case, once we had the flooding and vomiting under control. I did not think it safe even to give an anodyne to quiet the shock of such hemorrhage, believing better results would follow the nutrition, which was rapidly developing, once the stomach became settled.

The patient was extremely emaciated, from non-retention of food during the seven weeks since the abortion occurred.

Several days after tamponing, a characteristic discharge of a sero-sanguinous fluid, offensive in odor, came from the vaginal tract, and the remnant of Tannin which had not been absorbed was removed by simply using the finger.

Naturally, the sudden compression and contraction of the uterus in a state of hemorrhage, caught and retained within its cavity more or less blood, and this, with shreds adherent since the accident, being subjected to the requisite degree of temperature, were beginning to undergo decomposition. By this time the patient could be safely lifted upon a vessel and have the fountain syringe used to cleanse the parts, using about a quart of very warm water containing Zymocide ʒ j.

After being removed to bed I proceeded to use Osmotic treatment, as shown in the New York MEDICAL RECORD, May 27th.

Having selected a sponge of suitable size, and prepared as heretofore explained, with the aid of a speculum and forceps this sponge, saturated in water three parts and Zymocide one part, was placed in direct apposition with the os uteri, where, withdrawing the instruments, it was left for twenty-four hours. At the end of this time, the sponge, by means of the string attached, was withdrawn, saturated, as expected, with the débris of decomposing clots and shreds. The sponge being thoroughly cleansed in warm water containing a little spirits of ammonia, was again replaced, charged with the solution of Zymocide, directly to the os, and left as before.

This Osmotic medication was repeated every twenty-four hours, until, the amount of discharge brought away becoming daily less in quantity and more free from odor, it disappeared after eight or ten days, and as it rapidly and successfully fulfilled its mission, there has been no occasion for its renewal.

Perhaps the most satisfactory testimonial in favor of the treatment of this woman, so near the confines of the Great Hereafter, is the fact that, about a week ago, she walked into my office looking very little the worse for her siege.

She was still wearing an abdominal supporter, which she puts on in bed in the morning, and removes after she lies down for the night.

212 WEST THIRTY-FOURTH STREET,
August 18, 1893.

A NOTE ON THE DETERMINATION OF REFRACTION AND ACCOMMODATION.

BY EDWARD L. MEIERHOF, M.D.,
NEW YORK.

IN spite of the various appliances devised to measure the refraction and accommodation of the human eye with special reference to the objective method, and as there are quite a number of ophthalmologists who are satisfied with their findings as measured by the ophthalmoscope and ophthalmometer, the majority of eye practitioners prefer to rest their judgments on the determination of vision, in addition to other methods, by the subjective examination influenced by a mydriatic on all persons up to the age of decided presbyopia, also excepting myopes of a high degree and amblyopia from various other causes. Those who use the shadow test combine their determination with the subjective examination influenced by mydriasis. The objections of those who determine their findings by the ophthalmoscope and ophthalmometer are, that it saves time and relieves the patient of being subjected to annoyances of atropinization. This would seem to indicate that they have not become fully convinced of the utility of homatropine for the same purpose that atropine is used. Although homatropine has been in use as a cyclopegic over twelve years, there are numerous practitioners who still use atropine; yet we have had the published tabulated results of competent experimenters showing the reliability of homatropine for the purpose of paralyzing the ciliary muscle, serving all the practical purposes that can be obtained from atropine. Of late years a large number of the patients who consult the oculist are sent, not on account of any organic disease of the eye or apparent disturbance of vision, but for various disturbances to the nervous system, such as dizziness, headaches, nausea, etc. Many, if not most, of these patients have what is commonly accepted as normal vision. In theory the muscle of accommodation is at rest when looking at a greater distance than eighteen feet, whereas in practice we find such not always the case. It is this continued accommodation, known as ciliary spasm, which may mask an astigmatism or cause one, and for that reason no objective method can adequately determine the refractive state of the eye; therefore, those who practise putting the ciliary muscle in abeyance are bound to obtain the most exact findings in their refraction work. There are most competent men who claim to be able to measure the refraction by means of the ophthalmoscope, which no doubt in many cases can be done; however, I have subsequently seen some of those cases for whom cylindrical lenses were ordered who had no astigmatism; and on the other hand, astigmatism of two and three dioptrics was found which had been previously ignored. These cases usually occurred in those who had the standard normal vision,[1] and were usually subject to nervous disorders of the head. As previously stated, a large amount of the practice of the oculist consists in determining the state of the refraction and accommodation, and the examination of the ocular muscles with special reference to various sensory and motor disturbances of the nervous system, the former usually of the head. In view of the enormous amount of benefit that is frequently obtained by removing eye strain, this should be done with special regard to

[1] Emmetropia based on the fine minute angle.

the action of the ciliary muscle; but it cannot always be done by dependence on the objective method of examination of young hypermetropes, and in some cases of presbyopes. Regarding the use of atropine or homatropine, I have had no reason to complain of the results of the latter as a cyclopegic. In connection herewith I would like to state that I found it necessary to abandon the gelatine disks of homatropine, as I found they could not always be depended on, and in place I employ a three per cent. solution each of homatropine hydrochlorate (Merck's) and cocaine hydrochlorate in mucilage (U. S. Phar.), and this I have found eminently satisfactory, it seldom being necessary to instil more than once a large drop of this mucilaginous mixture to obtain the necessary paralysis of the ciliary muscle, when the gelatine disk caused unpleasant scratching by its mechanical presence until it was dissolved. With the mucilaginous mixture no annoyance in this particular is observed at all. I am aware there are some former advocates of homatropine who have in a measure given up its use, as they claimed its action was not always as efficient as atropine. I have not found this difference so material as to warrant the use of atropine, with its eight to twelve days effect, compared to the forty-eight hour influence of homatropine, except in the cases of young children, where the inconvenience of atropine is minimal.

Progress of Medical Science.

Composition of the Fœtal Urine Secreted in Utero.—Dr. Helme has made a communication to the *British Medical Journal* on this subject. He believes it important in that it provides the missing link of the chain of evidence that the fœtal urine is one possible and probable source of the amniotic fluid. Numerous analyses have demonstrated the presence of urea in the liquor amnii, the amount varying in different cases, but always increasing as gestation advances, and proportional to the size and weight of the fœtus. The presence of urea has been explained in three ways: 1, By transudation from the maternal structures; 2, by excretion from the fœtal kidneys and skin; and 3, from both these sources. Very few observations on the urine from the fœtal bladder have been made. Urine obtained from two sources, however, has been examined: 1, That obtained from the bladder of the dead born child; 2, that obtained by catheterization from the bladder of the live-born child. Analysis of these urines have demonstrated the presence of urea in each series, but in one case only has a quantitative estimate been made, by Gusserow-Wislicenus, the amount found being stated as 6.06 per cent.; probably, however, this is a printer's error, as has been suggested by Krukenberg; for von Ziemssen, in his "Cyclopædia," says: "On the other hand, when fluids have been abstained from up to a point when really unendurable thirst has been sustained, I have never found that more than 6.1 per cent. of urea was contained in the urine. The twenty four hours' urine of a strong, well-nourished adult, himself no great consumer of fluid, contains an average quantity of two or three per cent. of urea. Dr. Helme happened to be called to a lingering labor, in which he delivered the child with forceps (low operation). The child was a healthy full-time male, and was born head first. Immediately the breech was expelled, and before any attempt to breathe was made, the child began to micturate. The doctor seized the penis with one hand and a clean cup with the other, and then caught the remainder of the urine—just over half an ounce. This urine was carefully preserved and analyzed. For comparison he obtained another specimen of urine from the same child—six drachms—passed eight and a half hours later.

From the results of his studies the author submits the following propositions: 1. The fœtal kidneys secrete actively during intra-uterine life. 2. The urine of the normal living fœtus contains urea. 3. The urine of the normal living fœtus contains kreatinin. 4. The fœtal renal excretion is a possible source of origin of the liquor amnii; this is shown by the presence of urea and kreatinin in both these fluids 5. The presence of sulphates and phosphates in the liquor amnii, and their absence from the fœtal urine, would point to there being an additional source of origin of the liquor amnii. 6. The amount of urea and kreatinin excreted in the urine undergoes a marked increase during the first few hours after birth. 7. Kreatinin is normally present in the urine of the new-born child and suckling.

Recurrent Dislocations of the Shoulder-joint.—Dr. Richard believes that the present methods of treating recurrent dislocations of the shoulder joint are faulty. Both resection of a part of the capsule and of the head of the bone give fairly good results, but they do not allow complete restoration of the movements of the joint. In order to obviate this defect he has devised the following operation: The deltoid muscle is separated from the clavicular and acromial attachments by incision and turned backward as a thick flap, and an assistant retracts the coraco-brachialis muscle; by this means the attachment of the subscapularis to the humerus and the front of the capsule of the joint is laid bare. The upper and lower borders of this muscle are then forced from their attachments to the capsule. The arm being rotated inward, the operator now passes three strong silk sutures through the thickness of the capsule in front of the joint above and below; they are passed through the substance of the subscapularis muscle. The sutures are passed in a vertical direction, and placed about two centimetres from one another. The ends of the sutures are tied, and by this means the anterior wall of the capsule is made thick and rigid. The cut surfaces of the deltoid are approximated with sutures, and the superficial parts then sewn up. The nerve-supply of the deltoid is not involved in the operation and hence no paralysis follows.—*La Semaine Médicale.*

Microbes and Arrow Poison.—A French naval surgeon, Dr. Le Dantec, has examined the arrow-poison used by the natives of the New Hebrides. The results of his investigation have been published in the "Annales de l'Institut Pasteur." The New Hebrideans employ for this purpose earth from marshy places; it contains both the septic vibrio and the tetanus bacillus. From experiments on animals, it was found that when the poison was old, they died from tetanus; when fresh, from septicæmia. In the case of man, tetanus has always been observed. The practical outcome of all this is: wounds inflicted by poisoned arrows should be treated with every antiseptic precaution, and freely enlarged, if necessary, so as to remove all foreign bodies. The observations of Dr. Le Dantec are against the equine theory of tetanus, for there never have been horses in the New Hebrides. The author also draws attention to the fact that the Pacific Island savages were the first, and probably the only ones, to make use of "microbes in the art of war."—*Medical Magazine.*

Nail-biting among Children.—Dr. Berillon finds that the habit of nail-biting among children is extremely common. In a public school in Paris, out of 265 pupils examined during the month of April last, 63—that is to say, nearly one-fourth—were addicted to the practice. Curiously enough, results vary greatly in different districts and in different schools in the same district. It seems that girls are more given to the habit than boys. In one girls' school in the Department of Yonne, 11 out of 21 were confirmed nail-biters. In another girls' school the proportion was 61 out of 207 pupils, and, of those 61, 15 were found to be in the habit of biting the nails of both hands, and the others of biting only those of one hand. M. Berillon recognizes that nervousness has much to do with the habit.

THE YELLOW FEVER EPIDEMIC IN BRUNSWICK.

THE appearance of yellow fever in epidemic form in Brunswick, Ga., carries with it an impressive lesson, regarding neglected preventive measures, which should not be lightly regarded. There does now not appear to be any doubt that the first cases which occurred three weeks ago were not properly reported, and the result of such neglect of a plain duty is painfully apparent in the consternation, if not ruin, of the inhabitants of a once fashionable resort. It is also well known that the disease was brought this year to Brunswick, at the end of July, by two infected vessels from the West Indies, and that the immediate result was five deaths. Then the policy of concealment for business purposes obtained, and the result is as we have stated. It seems a great pity that such should have been the case when we consider how much nowadays can be accomplished by the early adoption of proper measures for staying the progress of this insidiously spreading and disastrously fatal epidemic. When we assume that the infectious agent of this plague is present in the dejecta of those suffering from the disease, and that accumulations of fecal matter and of other organic material of animal origin furnish a suitable nidus for the development of the germ when climatic conditions are favorable for its growth, it is easy to see that a removal from local influences, and the enforcement of thorough local sanitation, are the principal hopes for safety of those who are still threatened. The prompt establishment of camps away from the city, the enforcement of sanitary regulations by the health authorities, are proper, and would be proportionately more effective if they had been more timely. As it is, the stricken town may not be itself again until frost appears, and it will be a mercy if the disease, in consequence of the unprotected fugitives, is not spread to other localities.

THE VALUE OF THE EHRLICH STAINS IN THE STUDY OF DISEASE.

IN a recent editorial article we referred to the results obtained in studying the anæmias by means of the Ehrlich process of staining. Dr. William S. Thayer (*Boston Medical and Surgical Journal*, February 16 and 23, 1893) has gone over this subject very thoroughly, giving the technique of the method, and the results obtained by himself and others in other diseases than anæmia. Dr. Thayer believes that these methods can be used to a considerable extent by the clinician, and that one can, by their help, obtain additional data that may be most useful in diagnosis. We have not space to give here a description of the technique, but it may be said that a thin film of blood is obtained and dried on the cover-glass. This is then stained by certain acid aniline colors of which eosin is the type, and by basic anilines, such as methylene blue, and by a mixture of the two.

The acid color stains the red cells and certain granules in the leucocytes called eosinophiles; the basic color stains other granules in the white cells, called basophiles, and a third and most numerous type of granules, called neutrophiles, are stained by a mixture of acid and basic coloring matter, the acid being in excess. By means of these stains the leucocytes are differentiated into various forms. We have already given one classification. Several more detailed subdivisions are made by Uskow, Tschistowisch, and Ehrlich, but for practical purposes the division that may be used is that into (1) small, mononuclear leucocytes; (2) large, mononuclear, and transitional forms; (3) multiple neutrophiles, and (4) eosinophiles.

The red blood-cells may be divided into the nucleated and the ordinary forms. The former show variations in size and appearance which give evidence of degeneration or regeneration.

We have already referred to the results of the staining methods in the anæmias. With regard to general diseases Dr. Thayer states that in all acute inflammatory processes there is more or less leucocytosis. In tuberculosis, however, the blood examination shows that the anæmia of those cases is more apparent than real, and that there may be even a high proportion of red cells and hæmoglobin. This fact may be of service in distinguishing between tuberculosis and obscure malignant trouble of the abdominal viscera. In typhoid fever the blood examination may be of especial value. There is, we are told, a sharp falling off in the relative number of multinuclear elements, it may be under fifty per cent. This fall begins usually in the first week, is more sharply expressed in the second or third or even fourth weeks. The percentage of "over-ripe" elements begins to increase about three to twelve days after the disappearance of the fever. The percentage of the small mononuclear elements average only once and a half as much as that of the large mononuclear, instead of being normally three times as great. The decrease in the number of the multinuclear elements depends not so much on the parallel increase in the percentage of the small mononuclear leucocytes as on the increase in the percentage of the large mononuclear cells. This point appears to be one of considerable importance, and on various occasions Dr. Thayer has been able to make a probable diagnosis of typhoid fever when without the examination of the blood it would have been extremely difficult.

As regards pneumonia, the most valuable point shown is the fact that this disease is usually associated with an extensive leucocytosis, which is coincident with the fever. That in some fatal cases this leucocytosis has not been observed is of great interest, but of how much importance we cannot yet be sure.

Among other diseases which are generally associated with a leucocytosis, in which, however, no other impor-

tant changes have been noticed, are diphtheria, acute rheumatism, endocarditis, and small-pox.

In scarlet fever the blood-changes are such as enable one to gain some help in prognosis. Parasites and bacteria can for the most part be demonstrated by the Ehrlich stains.

THE COMPOSITION OF THE FŒTAL URINE SECRETED IN UTERO.

Dr. T. Arthur Helme has recently made (*British Medical Journal*, June 17th) an observation which he considers of importance, in that it "provides the missing link in the chain of evidence" that the fœtal urine is a possible and probable source of the amniotic fluid. It has long been known that the latter contains urea, the amount varying, in general terms, directly according to the period of gestation and the size and weight of the fœtus.

It is pointed out that this urea may come from transudation from the maternal structures, by excretion from the fœtal skin and kidneys, or from both of these sources. It is, furthermore, somewhat surprising that the literature of medicine does not contain a single analysis of healthy fœtal urine, or urine from the bladder of a healthy child before it has breathed. Here has been the missing link, the lack of positive evidence that the urinary secretion of the normal fœtus contains any urea. Urine was obtained from the bladder of a still-born child, but this was post-mortem urine and had presumably undergone certain changes. Urine also obtained by catheterizing the newly-born child fails to respond to the requirement, because it is not the product of a child which has never breathed.

I happened, says Dr. Helme, to be called to a lingering labor, in which I delivered the child with forceps (low operation). The child was a healthy full-time male, and was born head first. Immediately the breech was expelled, and before any attempt to breathe was made, the child began to micturate. I seized the penis with one hand and a clean cup with the other, and then caught the remainder of the urine—just over half an ounce. This urine was carefully preserved and analyzed. For comparison I obtained another specimen of urine from the same child—six drachms, passed eight and a half hours later.

The first specimen, it will be seen, fulfilled the condition of true fœtal urine, because at the time of its passage the child had not yet breathed.

Examination of the two specimens showed that neither contained sugar, albumin, nor phosphates. The first specimen contained no sulphates, while they were present in the second. Both had chlorides, urea, and kreatinin, the latter being present in larger amounts in the second specimen.

An examination for urea by the sodium hypobromite method showed 0.66 grain of urea per ounce in number one, and 1.32 grain per ounce in number two; that is, urea is present in considerable quantity in the urine of the normal living fœtus. It follows, therefore, that this urine is a possible source of the urea found in the liquor amnii, and that the fœtal renal secretion is a possible source of the liquor amnii itself. Kreatinin is known to be present in small amount in the amniotic fluid, but its presence in the fœtal urine is especially interesting.

It will be seen, therefore, that there is pretty conclusive evidence that the liquor amnii is, in part at least, fœtal urine. Dr. Helme concludes as follows:

1. The fœtal kidneys secrete actively during intra-uterine life.

2. The urine of the normal living fœtus contains urea.

3. The urine of the normal living fœtus contains kreatinin.

4. The fœtal renal excretion is a possible source of origin of the liquor amnii; this is shown by the presence of urea and kreatinin in both these fluids.

5. The presence of sulphates and phosphates in the liquor amnii, and their absence from the fœtal urine, would point to there being an additional source of origin of the liquor amnii.

6. The amount of urea and kreatinin excreted in the urine undergoes a marked increase during the first few hours after birth.

7. Kreatinin is normally present in the urine of the new-born child and suckling.

THE SURGICAL EXHIBITS AT THE WORLD'S FAIR.

The *Medical Standard* begins its editorial page with the following remarks, heavily leaded:

"Visitors to the World's Fair will find the principal exhibits of medicinal preparations, surgical instruments, and other displays of especial interest to physicians, in the gallery of the Manufactures and Liberal Arts building. This announcement is due both to the medical profession and the exhibitors, since there are so many objects of interest in the vast area of the ground floor that the equally important display in the gallery is too often forgotten. The gallery is easily reached by numerous stairways, and in the variety, beauty, and richness of its exhibits will compare favorably with, if not excel, the other treasures of the great exposition. The medical, pharmacal, and surgical exhibits are a treatise, every page of which is replete with interesting demonstration of the marvellous evolution of medicine."

A correspondent of *Le Progrès Médical*, Dr. M. Baudouin, writing from Chicago, tells a somewhat different tale. He begins with the statement that the medical congress which met in Chicago (?) last May was a failure, partly because physicians from the East did not attend, and partly because of the diversion caused by the prospective congresses in Washington and Rome.

He then directs his attention to the medical and surgical exhibits at the Fair. These do not, he says, compare at all favorably with the similar class shown at Paris in 1887. Only two large surgical houses had exhibits of much value. "The New York and Philadelphia surgical firms did not think it worth while to have themselves represented." The present exhibit consists of a "motley assortment of bandages, trusses, and glass work, which show only too well the American habit of sacrificing everything to the useful." "What a difference," he adds, "from our Parisian products!"

There are some surgical instruments which are "sufficiently original," but these are few. Most of the apparatus is essentially the same as that in Europe. The surgical instruments, he adds deprecatingly, are cheaply nickle plated. As compared with Parisian instruments,

the American are less artistic, less elegant, and more clumsy. He refers here to the ordinary surgical instruments. As regards prothetic apparatus, the French "remain the masters." Unhappily, he says, the Americans prefer cheap instruments. "It is only the surgeons of the Eastern hospitals who know how to appreciate the real value of elegance and the merits of Parisian productions."

The trouble with the Western surgeons, says M. Baudouin, is in brief that they have never seen a good thing, and hence do not know that they haven't got it. Furthermore, "by reason of the patriotic vanity" [so conspicuously absent in the French] "which is the characteristic of the Yankee, he believes that whatever he possesses must be the very best."

The Columbian Exposition, says our philosopher, will do more harm to Americans in general than it will do good to Chicago. For it will enable Europeans to dissect the industrial production of the United States and will show that, apart from a few special things, such as means of transportation and lessening of hard labor, Europe is vastly ahead." We have, he says, been led to have some credence in the wordy prospectuses seasoned *à la Marseillaise* which have been put forth; on testing them we find some deceptions."

The criticisms above quoted are thoroughly French, and may be taken with much salt. Yet there is perhaps some truth in them.

The "patriotic vanity" of the Yankee will receive some comfort from the following comments, made by an English critic who writes to the *British Medical Journal*.

"The World's Fair at Chicago is replete with interest to everyone, and especially to medical men, sanitarians, and social observers. For, apart from its general artistic and industrial features and the unrivalled architectural and landscape attractions of the Chicago exhibition, its ethnological, demographic, and medical and surgical exhibits are of surprising extent and completeness; and furnish abundant material for those who care to unite intervals of serious study with general sight-seeing on a great scale. In anticipation of the needs and wishes of those who may now be disposed to substitute an American tour for the Roman pilgrimage, I forward some details which may readily be supplemented from the usual sources."

The Time of Profit.—

I love the pleasant time between
The growing time and riping,
When vines and trees all burst in green,
And little birds are piping.
When on the apple-tree the fruit
Bears promise of fruition—
Until the small boy starts to root—
You see I'm a physician.

A Ripe Old Age.—Mrs. Margarita Rivera, grandmother of Governor Calan, of Coahuila, died at Monterey, Mexico, at the age of one hundred and thirty-two. She was born in Spain, and came to Mexico over a century ago. She recently received from the Archbishop, at Madrid, a copy of the Cathedral record of her birth. Her health for the past several years had been very feeble, and she was confined to her room.—*Annals of Hygiene.*

News of the Week.

Medical Society of the State of New York.—The following Business Committee has been announced by the President of this Society, Dr. Bendell: Dr. Henry Flood, of Elmira; Dr. L. Bolton Bangs, of New York; Dr. Edward Clark, of Buffalo. Communications regarding papers for the next meeting of the Society, February 6, 1894, can be addressed to them. F. C. Curtis, M.D., *Secretary.*

The Cholera.—The latest reports show that cholera is very widely distributed throughout Europe, and is still slowly spreading. The disease exists in Russia, Bulgaria, Germany, Austro-Hungary, Galicia, the Netherlands, France, Belgium, Italy, Smyrna, and, lastly, in Constantinople. As regards England, outbreaks or isolated cases have occurred at Grimsby and Hull, and, it is alleged, at Bradford, Sheffield, Rotherham, and Belfast.

Dr. Anton Weichselbaum has been appointed Professor of Pathological Anatomy and Director of the Institute of Pathological Anatomy in the University of Vienna.

Dr. Carl Beck, of this city, desires us to state that his remarks on page 378 should read, "I do not, however, approve of the method of resection in sero-fibrinous exsudations, as recently recommended in Germany."

How the Charity Patient got the better of the Surgeon.—A young man was admitted into the Jewish Hospital at Buda-Pesth, so badly injured that the surgeon decided to perform an operation upon him. While beginning to operate on the patient's left arm the surgeon looked at his watch, and after finishing with the case he noticed that his watch had been stolen from him by the patient's right hand. The thief was handed to the police for the continuation of "treatment." Fortunately, the surgeon recovered his watch, but unfortunately lost a patient.

A Post-office Ruling Regarding Disease Germs.—The *Boston Medical and Surgical Journal* for August 24th, states that the Postmaster-General has made a ruling that disease germs are to be classed with unmailable articles, no matter how securely they may be sealed.

The Second Pan-American Medical Congress.—The affairs of the next Pan-American Medical Congress are placed in the hands of an international executive committee, one member from each country, and that committee decided that the next meeting shall be held in the City of Mexico, at a time yet undetermined. It is probable that the winter season will be selected, and that the Congress will be held five years from this date, with Professor Rafael La Vista, of the University of Mexico, as its President.

Professor Pasteur has been elected honorary member of the German Medical Society of New York City. His letter of acceptance was read before the Society at the meeting on September 11, 1893.

The Congress on Medical Jurisprudence met in Chicago August 14th. It was sparsely attended, and attracted but little attention. Most of the medical congresses have been utter fiascos.—*Medical Standard.*

The Chicago "Keeleyites" are at war. The "Graduate" claims that Keeley pours his financial favors on the "Banner of Gold," albeit the "Graduate" has sent

"hundreds to Dwight." The "Banner of Gold" has in its corps several "journalistic" exploiters of Keeleyism in the daily press. The "Graduate" charges these with having received from Keeley an undue amount of cash as a reward for their "faithfulness to the cause."—*Medical Standard.*

The Illinois State Board of Health deserves credit for the recent decided step it has taken in the best interests of the profession. The London Polyclinic and the Chancellor Remedy Company some time ago made application to the Secretary of State for license to incorporate. The objects of the proposed corporation were stated to be the treatment of diseases, the prescribing of medicine, and the performance of surgical operations. Dr. Scott, Secretary of the State Board of Health, upon learning of the applications, protested against the issuance of licenses, on the ground that the objects stated were not sufficiently explicit.

Trephining in the stone age was done, according to Dr. Munro's *Fortnightly Review*, by scraping the skull with a sharp flint, though there is occasional evidence of its use in a sawing manner, such as obtained when the ruder implement was superseded by one of metal. The process was almost exclusively practised upon children, probably on account of the facility with which it could then be accomplished, and probably also as an early precaution against those evils for which it was esteemed a prophylactic. What the dreaded evils were, was suggested by Dr. Broca, who while he believed that the operation was primarily conducted for therapeutic purposes, saw behind these the apprehension of a supernatural demoniacal influence.

Experimental Physiology on the Human Subject.—An advertisement recently appeared in a New York daily, offering $5,000 to any man who would submit to an experimental surgical operation involving some risk. One hundred and forty-two answers were received. It is said that two physicians in Ecuador are the advertisers, and that they wish to establish a gastric fistula, and repeat the observations made by Beaumont on St. Martin.

Relief for Hay Fever.—The capriciousness of hay fever, and the occasional relief obtained from an entirely empirical method of treatment, warrant the publication of any means which has proved successful, in the hope that it may be of use to some other person afflicted with this annoying and disabling disease. Feber, of Hamburg, reports his own case, which had been so severe as to necessitate his using a closed carriage all through the summer. His relief was brought about from accidentally noticing that in the winter a coryza was usually accompanied with hot ears, which regained their normal temperature when the discharge from the nose was established. He determined to try a reversed order of effect on the hay fever in the summer, and began accordingly to rub his ears until they became red and hot. It is now the third year that he has been able to lead an endurable existence during hay-fever season. "As soon as the least sensation of fulness in the nose appears, there is recognized a certain amount of pallor in the ears. A thorough rubbing of the ears, at times even to contusion, has always succeeded in freeing the nasal mucous membrane from its congestion. The rubbing, however, must be thorough and repeated as often as the least symptom of congestion returns to the nose. Since using this means I have been able to take long sandy walks, sit and even sleep with open windows, or pass an evening in my garden without distress. Several patients have had the same relief from this treatment, always in proportion to the thoroughness of the rubbing, and I hope by this means some other physician may be able to give his patients the same great relief."—*Boston Medical and Surgical Journal.*

Doctors' and Lawyers' Fees.—We had a great excitement a few weeks ago in San Francisco (*Pacific Medical Journal*). Men who scarcely knew each other and were in the habit of passing with the slightest recognition, stopped, clasped each other's hands, looked earnestly into each other's faces, spoke in a subdued tone of voice, and showed all the evidence of having heard portentous news. Nothing else was talked of at the clubs, chestnuts were at a discount, and even club scandal was neglected for the time. The great daily papers as well as the weekly news scavengers lent their assistance to fan the popular excitement. John W. Mackay, the many times millionaire, had been shot by a would-be assassin; this, however, was not the cause of the excitement (shooting a man, even a millionaire, in California, has long since ceased to be a novelty). The excitement was about the fact that two medical gentlemen who extracted the bullet and saved the millionaire's life had charged him $12,500. For the too little sympathy that the millionaire received when he was shot, everybody, press and paper, made up for the neglect now. Millionaires congratulated each other that they were not in need of medical service, and hoped when their taking-off time came, their departure would be a sudden one—no chance for a physician to wreck their estate. The foolish fellows in their excitement forgot that their estates were in no danger of being wrecked, forgot that their attorneys would protect them. Since recovery from his wounds and the $12,500 indignation shock, he has asked the Probate Court for permission to distribute the property and close an estate for which he was executor. Among the items of expense which he incurred as executor of this estate is attorney fees $26,160; for what? for piloting this will through the Probate Court, an automatic procedure that required neither skill, ability, learning, nor judgment. Will John W. Mackay explain why he was willing to allow the attorney $26,160 for the service rendered, and refused to pay his physicians $12,500 for services that required much more individual skill and judgment and a thousand times more responsibility on their part than was required of the attorney? The $26,160 item created no excitement, but one newspaper seems to have noticed it, and congratulated the attorney on having received a good fee. Perhaps the daily or weekly press will explain why a millionaire should not pay a physician as liberally as he does an attorney. Another attorney of this city is receiving the congratulations of the press and his friends on the receipt a few days ago of a fee of $75,000. The attorney received one-fifth interest in the estate, which was then involved in litigation. What would be thought of a physician who would undertake to cure a patient for a certain interest in his (the patient's) estate?

A Death from Chloroform.—A sudden death occurred on the 20th instant, as the result of the administration of chloroform in the Seney Hospital. The patient was a male, aged fifty-five, who had a dislocation of the shoulder. The house-surgeon advised against the administration of an anæsthetic, but the patient persisted to the contrary. After a few whiffs of the vapor he suddenly expired with cardiac paralysis. It is a question if ether would have had the same effect. At all events it proves chloroform to be a dangerous and tricky agent under the circumstances, and will add another experience to the danger of giving it the benefit of a doubt when a safer anæsthetic is at hand.

To Investigate the Coroners.—The Grand Jury of this city has issued subpœnas for the coroners to appear and answer the numerous charges of neglect of duty in not responding more promptly to calls for their services.

Clinical Instruction in Contagious Diseases.—The story comes to us that two young physicians, who were pupils at the Vanderbilt Clinic, have been stricken with small-pox as a result of a clinical lecture on a supposed case of varicella. Aside from the sad outcome of the venture, an impressive lesson is thus given regarding the necessity of educating medical men to a better knowledge of the contagious diseases than now obtains, and also under circumstances of proper precautions against spreading the contagion. But what excuse has a teacher for being so ignorant of the general symptoms of small-pox as to make such a mistake possible? Those who may escape the contagion will at least congratulate themselves that they have seen one real case of small-pox. In the meantime, however, the disease is liable to spread in many heretofore unsuspected localities. It will be worth while for those gentlemen in charge of clinics and dispensary classes to be careful for a while how they diagnosticate supposed cases of chicken-pox.

Obituary.

HENRY B. MILLARD, M.D.,

NEW YORK.

A CABLEGRAM from Paris announces the death in that city of Dr. Henry B. Millard, on September 14th. Dr. Millard was born in Oneida County, New York, sixty-one years ago, and was graduated at Hamilton College in 1855. Three years later he was graduated from the medical college of the University of the City of New York. He entered upon the practice of medicine in this city. Afterward he became a homœopathist. In 1887, however, he returned to the regular school, and became a fellow of the Academy of Medicine of New York and of the American Academy of Medicine. He was also chosen foreign corresponding member of the Academy of Medicine of Paris, of the Verein Deutscher Aerzte of Prague, of the Société d'Hydrologie Medicale, of Paris, of the Royal Academy of Medicine of Rome, and an honorary member of the Société Anatomique of Paris.

At home he became a member of the New York County Medical Society, the New York Pathological Society, and the New York Society of Medical Jurisprudence and State Medicine. He was also professor at the New York Medical College and Hospital for Women in West Fifty-fourth Street, and a member of the State Board of Examiners. Most of his foreign honors were won for him by his published books and essays, and especially by his treatise on Bright's disease of the kidneys, for which he received the gold medal of the New York Medico-Chirurgical Society in 1884.

For the last twenty years Dr. Millard had spent all his summers in Paris. He had been ill from typhoid fever.

EDWIN N. COLT, M.D.,

BROOKLYN (E. D.), N. Y.

DR. EDWIN N. COLT, who was regarded as the oldest practising physician in this State, died recently at his home at 85 Morton Street, Williamsburg, in his eighty-third year. He was born in Hinsdale, a small village near Pittsfield, Mass., on August 7, 1811, and in his early years was educated by the dominie of the village church. Afterward he attended the Wilbraham Academy at Wilbraham, Mass., and, in 1828, entered the Berkshire Medical School. He was graduated in 1832, and associated himself with hospitals in Albany. Sixty years ago he went to Williamsburg, where he practised up to the time of his death. It always gave him pleasure to describe his first visit to Williamsburg. He said he got on a boat at Peck Slip, this city, and a treadmill, worked by a horse, was the motive power. Williamsburg's population was then only about four hundred and fifty, and there were but four doctors in active practice.

WILLIAM T. WHITE, M.D.,

NEW YORK.

WE regret to announce the death, on September 17th, of Dr. William T. White, aged sixty-four years. Dr. White was a man whose character was highly esteemed, and whose services to the medical profession have been very great. His career was an active one, and he will always be closely identified with the medical history of this city and State.

He was born in Richmond, Me., and was graduated from the New York Medical College in 1855 after a preliminary course at the Bowdoin College Medical School.

He was afterward demonstrator of anatomy at Bowdoin. His professional activity is well shown by the various positions of responsibility which he occupied. For eight years he was chief surgeon of the Panama Railroad on the Isthmus. For twenty six years he was a member of the New York Academy of Medicine, being at different times its Secretary and Vice-President. He was also a member of the County Medical Society, the American Medical Association, trustee of the Geneological and Biographical Society, and one of the founders of the New York State Medical Association and the New York Physicians' Mutual Aid Society. He was also Vice-President of the New York Medico Historical Society and one of the board of managers of the New York Society for the Relief of Widows and Orphans of Medical Men.

For fifteen years Dr. White was attending surgeon at the Demilt Dispensary. He was formerly visiting surgeon at the Presbyterian Hospital and the Charity Hospital on Blackwell's Island. For twenty-one years he was attending physician at the Home for the Relief of Aged Indigent Females. In late years he was best known as the editor of the Medical Register for New York, New Jersey, and Connecticut. He was also, though not himself a veterinarian, the President of the New York College of Veterinary Surgeons.

PROFESSOR LYMAN BARTLETT HOW, M.D.,

HANOVER, N. H.

PROFESSOR LYMAN BARTLETT HOW, M.D., of Manchester, died in Hanover, N. H., on Friday, September 15th, of consumption. He graduated from Dartmouth in 1860, and from the medical department in 1863. He had been Professor of Anatomy at Dartmouth for twenty-five years, and held the place until this year, when failing health compelled him to give it up. Dr. How was fifty-five years old, and leaves a widow and two daughters.

Society Reports.

Pan-American Medical Congress.

First Meeting, Held at Washington, D.C., September 5, 6, 7, and 8, 1893.

(Special Report to the MEDICAL RECORD.)

(Continued from p. 381.)

THIRD DAY, THURSDAY, SEPTEMBER 7TH.

SESSION called to order at 9.30 A.M. Prayer was offered by Rev. George Elliott, D.D. A brief response to the Congress on behalf of Venezuela by Dr. Rivero Soldivia. MR. ERNEST HART, of London, was introduced and spoke in substance as follows:

Qualifications for Success in Medicine.—Sir Astley Cooper, who was the model of a brilliant surgeon and an accomplished gentleman, was accustomed to give to every candidate for graduation from the London College of Surgeons the following advice: "You are about to enter upon a noble and difficult calling. Your success will depend upon the possession of three things: First, knowledge and the habit of systematic study; second, continual industry; and third, moral character. Without the first, no one can wish you to succeed. Without the second, you will never be able to succeed. Without the third, if you do succeed, your success can bring you no happiness." This advice is an admirable summary of all text-books on the private and public conduct of medical men. Nothing more than this is really necessary, and a vital question both in England and the United States at the present time is, whether it is necessary to add anything definite to the rules laid down by the great English surgeon.

Code of Medical Etiquette.—This question has until recently been regarded as answered in the negative, but under the stress of modern civilization, of competition, and of the temptation to advertise in various ways, it has been reopened and calls for new discussion.

Such a code as does exist has a strong and logical basis. It exists no more for physicians than for the public. It does not rest upon a trades-union spirit. Such a spirit has been erroneously attributed to it by the public, who have stigmatized it as an evidence of narrowness.

Etiquette of the Law.—The medical profession is but one of many. The legal profession has its code, which is enforced by the discipline of the bar. It provides that any lawyer who is not, in the broadest sense, a gentleman in all his dealings with his fellows, should be by them avoided. The claim that a code limits the liberty of a legal practitioner is propounded only by those who would turn liberty into license. Liberty is a blessed word, but compulsion is often a much more blessed word.

Necessity of a Medical Code.—Can all the precedents of the past be cast aside? Can all the "case law" of the daily complications of medical life be disregarded? If physicians were purely abstract moral creatures the golden rule alone would suffice as a code. But it must be remembered that men are not perfect, and that without a particularized code even the best of them are apt to decide wrongly in their own favor doubtful points, even where medical "case law" exists applicable to such instances. To enter on a medical life is a mission as well as a mode of living, and there is demanded the spirit of self abnegation which alone crowns missionary effort.

London College of Physicians.—This body has a board of Censors who are called upon to decide in all cases where its members may complain that the spirit of medical ethics has been violated by their associates. The rules of these Censors have not been regarded as perfect, and additions thereto have been made as the conditions of modern medical life have seemed to demand. The Medico ethical Section of the British Medical Association simply elaborates the rules of the London and other colleges.

Consultation with Homœopaths.—There is no logical basis on which we can meet any men who practise exclusively one system of therapeutics. Their position is an abnegation of reason, and as well might the Catholic and agnostic meet at the bedside of a dying man to offer him the consolations of religion. Nor is there, moreover, any reason whereby a consultation should be held merely for purposes of diagnosis. We do not meet at the bedside to answer riddles or solve conundrums. The medical man is primarily a healer, and the same rule of non-association should govern in surgical as well as medical cases.

Modern Quacks.—Johnson's dictionary defines a quack as a boasted pretender of a knowledge of physic which he parades in public places. The possession or non possession of a degree is no essential condition of quackery; but the latter is rather embodied in a love of advertisement and boasted pretension. Such men want no code.

The modern quack is one who allows himself to be interviewed by the public press. Through its columns he proclaims his views on new methods of treatment, new drugs, new operations, and the latest new alkaloids and antitoxines. If he attends a prize-fighter or a ballet girl, or the President of the United States or any other statesman, he unfolds through the ubiquitous reporter the secrets of the sick-room. Thereby is he false to the Hippocratic oath, which is binding in the conscience of every conscientious physician. He tampers with secret remedies, and frequently derives pecuniary profit from their sale.

The Public as well as the Profession Benefited.—All such courses are condemned by a proper code. Such a condemnation provides alike for the safety of the public as well as harmonious relations between medical men. The true physician conceals no useful knowledge from his fellows. The discoverer of a new remedy is like a clergyman who discovers a new dogma or doctrine in new religion which assists to salvation. Any physician who sells his birthright for a mess of pottage is false to his profession, a traitor to himself, and a traitor to humanity.

A motion was introduced and carried, to the effect that the members of the International Committee be continued in office till their successors be appointed, and that they be authorized to appoint sub-committees which shall represent each country sending delegates to the Congress as may be necessary.

The following resolutions were presented from the Section on Hygiene, Climatology, and Demography:

"*Resolved*, That it is the sentiment of this section that in view of the prevalence of Asiatic cholera in Europe at the present time, and the constantly increasing number of foci of infection, immigration from European countries in which cholera exists should be temporarily suspended, as this action affords, in our opinion, the only certain means of averting a threatened invasion by the disease of the countries of the American continent;" and

"*Resolved*, That the resolution be reported to the general session of the Pan-American Medical Congress, with a request for its adoption and speedy transmission to the executives of the several countries officially represented therein."

These, with another resolution requesting a reprint of Dr. Shakespeare's work on cholera for distribution among the countries represented in the Congress, were referred to the International Executive Committee.

FOURTH DAY, FRIDAY, SEPTEMBER 8TH.

Prayer was offered by REV. BYRON SUNDERLAND, D.D.

Owing to the absence of Dr. J. B. de Lacerda, of Rio de Janeiro, his address as announced on the programme was omitted.

Brief addresses were made on behalf of the Republic of Columbia by DR. GARCIAS, and the Republic of Honduras by DR. FERD. C. VALENTINE. The latter said that Honduras was a small country with a large debt,

but it possessed a salubrious climate, and is furthering the cause of education, the liberty of the press, life's great post graduate school.

The report of the International Executive Committee was next read. It was, in the main, a statement of what had been done in executive session with reference to the various resolutions which had been referred to it.

The resolution from the Section on Hygiene, Climatology, and Demography regarding the appointment of a cabinet health officer, as reported in the session of the previous day, had been adopted by the Committee, and the secretary was requested to inform the several governments of this action.

The number of sections was reduced by combining several with each other.

The Committee decided to hold the next Congress in the City of Mexico, in either 1896 or 1897. The exact date was not settled upon, owing to the uncertainty as to when the next International Congress might be held.

In regard to the resolution relative to the suspension of immigration from cholera-infected countries, the Committee decided that it was unwise in their judgment to take action thereon at the present time.

It was further voted to publish the address of Dr. Pepper, the President of the Congress, in advance of the regular transactions. A resolution was adopted from the Section on Pharmacology, providing that a society should be formed for the purpose of studying the American flora from a medical point of view, and for the establishment of a Pan-American pharmacopœia; also for providing for a uniform standard of medical education in the various countries.

Dr. A. L. Gihon, United States Navy, introduced a resolution providing for the disinfection, without discrimination, of all baggage of immigrants, dunnage, and crews of immigrant vessels entering American ports, thereby making doubly sure the precautions now taken at points of departure; furthermore, that these measures should be carried out at all times, and not merely during the prevalence of epidemics.

The thanks of the Congress were voted to the President of the United States, Congress, the officers of the Army, Navy, and Marine Hospital Service, general and section officers of the Congress, the local committee, lay press, and transportation companies.

In closing the final session brief addresses were made by the Hon. James C. Phillippo, M.D., of Kingston, Jamaica, on behalf of the southern countries, and by Mr. Ernest Hart, of London, on behalf of the foreign visitors.

Dr. Pepper spoke a few closing words defining the scope of the Congress in relation to the work of the American Medical Association and the various special societies in the United States. He believed now that the work of organizing the medical profession of the Western hemisphere was completed.

The Congress then adjourned.

SECTION ON GENERAL MEDICINE.

Third Day, Thursday, September 7th.

Filaria Sanguinis Hominis.—The meeting was opened by a paper on this subject by Dr. P. G. de Saussure, of Charleston, S. C., who said the disease is increasing in Charleston. The negro is more liable to the disease. It is not hereditary. It is more common in the lower classes. There is no diagnostic symptom. It can only be found by examination of the blood. It has been found in a number of patients who had no symptoms. The method of infection is not known. It has been supposed that it is carried by the mosquito.

The author read histories of 33 cases who had symptoms as follows: 24 had chyluria or hæmato-chyluria; 14, lumbar pains with abdominal colic; 13, intestinal dyspepsia with diarrhœa; 10, heart murmurs with rapid pulse; 7, lymphangitis and cold abscesses; 4 fever and chills; 12 had chylocele.

The chief danger to life is that the adult worm may become lodged in the heart.

Two of the cases only proved fatal. The embryo was only found at night. Treatment was not successful in curing the disease in any case.

The paper was discussed by Drs. G. E. Fell, of Buffalo, N. Y., J. Gardiner, of Indiana, and J. M. Postle.

Dr. V. C. Vaughn said that the geographical distribution was quite well marked. He considered the paper a very valuable contribution.

Dr. de Saussure closed the discussion.

Cholera Asiatica, 1892.—By Dr. J. Drummond Burch, of Aurora, Tex., was the second paper. He dwelt on the following points: So long as the mud of the Ganges is sacred, so long will cholera trouble the earth. During the Sepoy rebellion native troops were governed by grades of caste. The great difficulty is in transacting ordinary business while carrying out sanitary laws among a population so resembling their sacred river, its fifteen hundred miles of "variety of phases," having its source in the nail of the great toe of Vishnu's left foot. This endemic of India was first noticed in Djelalabad, Afghanistan, a town largely Hindoo, in December, 1891. Pilgrims carried it to the great Hurdwan Fair, about two hundred and fifty miles north of Lucknow, by March or April, 1892. Thence, "commerce having been engrafted on religion," it traversed much of the route of 1831, as shown by Surgeon-General Cornish. Dr. Grebentschikoff affirms the present epidemic is a continuation of a pandemic which began its course in 1881. The Golden Horn was frozen over, the first time since 1849. The coldest winter known in Europe, for years, did not arrest it. The Paris epidemic not believed by some to be directly connected with this epidemic travelling from India. Filth does not generate cholera, nor cleanliness exempt from it. The most generally accepted theory is that Koch's comma bacilli are the cause. Semmola says this doctrine at best is based only on a hypothetical basis, and results that are established solely in the laboratory. Malignant epidemics of cerebro-spinal meningitis, typhoid and typhus fevers, have their causes in unhygienic conditions; cholera and the eruptive fevers seem to be confederated through the germ theory, of which so much and so little is known. One may breathe small pox; he must swallow cholera. What will affect man does not affect lower animals. Man alone of all living creatures is susceptible to the cholera virus. Hoffkine's demonstrations to show the value of anti-cholera vaccine, 400 in India, without any untoward symptoms. Koch says comma bacilli die quickly when dried. Comma bacilli lately discovered in intestines of flies. Bacteria may be carried by paper money. Drs. Acosta and Rossi, on two notes of the bank of Spain, weighing about fifteen grains, estimated 19,000 septic germs of various kinds. Dr. Reiche notes the difference in symptoms in the epidemic at Hamburg and those already known. Petechiæ or ecchymosal spots over the bodies of some cases, as seen principally over the joints of sufferers in the epidemic of cerebro-spinal meningitis in Texas in 1890, in which all cases were complicated by articular rheumatism. Enteric fever as a complication rarely seen at Hamburg. Opposed to cremation because of peculiar morbid anatomy of cholera. Reiche thinks Koch's discovery confirmed at Hamburg. The hypodermoclysis and enteroclysis of Cantini. Surgeon Lieutenant-Colonel Lewins, M.D., says his father originated the saline rectal and venous injections in 1832, so "new" to some modern writers In discussion Macnamara says, if laudanum must be used to retain comma bacilli in intestines of a guinea pig for experimental purposes, is it not a good argument against its use in treating the disease in man? Strong argument for inoculation is the fact that persons once affected by cholera are somewhat immune. A note received from Sir Andrew Clark, M.D., on treatment, stated that he believed that every case must be treated on its merits, and that no one plan was to be recommended.

Dr. Fullerton, of Columbus, O., said that cholera

should be treated by quinine, gr. ten, every hour for three or four doses. He said that he believed this amount would inhibit the growth of the bacilli in the intestine.

The Part Taken by the Medical Profession in the Discovery of America was the third paper, read by Dr. A. M. Fernandez de Ybarra, of New York. Due credit has never been given to the medical profession for its part in this great event. The intentions of Avicenna, the advice of the Florentine physician, Paul Toscanelli, to Columbus, the opinion of Dr. Garci Fernandez, of Palos de Moguer, to the Prior of the monastery of La Rabida, the report of Dr. Chauca, who accompanied Columbus in his second voyage, paying with his life his professional devotion, are sufficient evidence that physicians took an active part in the discovery of America.

There was no discussion of this very interesting paper.

Afternoon Session.

Clinical Notes on Amœbic Dysentery, by Dr. H. A. West, of Galveston, Tex. He said: Attention is called to the practical importance of the subject in consequence of the diversity of opinion in regard to the definition, varieties, and etiology of dysentery, and especially the non recognition by the general medical profession of the casual relations of the amœba colli in the production of dysentery and the wide dissemination and frequent occurrence of this form of the disease.

Attention is also called to the following points: 1. Importance of a correct definition. Dysentery is not, as is usually taught, a morbid entity, consisting of an inflammation of the large intestine, essentially the same in all forms and climates, varying only according to climatic and other modifying conditions; on the contrary, the term dysentery should be used in a general sense to express a group of inflammations of the large intestine, partly of specific and partly of non-specific origin. 2. The adoption of the following classification will do much toward dissipating the existing confusion, viz., acute catarrhal, acute diphtheritic, amœbic, and secondary dysentery. 3. Amœbic dysentery is more widely disseminated and occurs with greater frequency than is generally supposed. 4. To emphasize the probable entrance of the amœba through impure drinking water. 5. To note the characteristic and uniform symptoms of this form of dysentery. 6. The essential chronicity and difficult cure depending upon the character and location of the lesions. 7. The necessity of combating the excessive anæmia and wasting by the use of a more liberal diet than is generally prescribed. 8. To urge the importance of cleansing and antiseptic irrigations as a rational method of reaching and destroying the amœba, and stimulating the intestinal ulcers to heal. 9. To note the fact that while solutions of quinine are destructive to the amœba, injections of the same fail to exercise any marked curative effect. 10. His experience goes to show that mild injections of nitrate of silver, thirty grains to a quart, with occasional administration of salines and large doses of bismuth and salol constitutes the best treatment. Details of seven cases illustrative of the above points treated in the John Sealy Hospital, Galveston, Texas, from October, 1892, to June 1, 1893, show the comparative frequency of this form of dysentery in this locality; there were only two or three cases of catarrhal, and none of diphtheritic or secondary forms admitted during this period. Two of them originated upon the same steamship in Vera Cruz, the facts strongly pointing to infection through the drinking-water. One acquired the disease while travelling through Indian Territory and North Texas, one was from Arkansas, having lived for some time in the alluvial bottoms of the Mississippi and Red Rivers. These two also drank impure and stagnant water. The other three cases originated in Galveston, or its immediate vicinity, and no history of infected water could be obtained. The symptoms in these cases were very uniform; though they might begin acutely they would very soon become chronic, and are characterized by irregularity in the flux as to character and frequency of the stools, alternating between improvement and relapse; the difficult cure and chronicity depending upon the nature of the lesions, viz., ulceration of different portions of the large intestine and sometimes of the ileum, with a disposition to infiltration and undermining of the mucous membrane, affording a nidus for the development, growth, multiplication, and destructive work of the micro organisms. The nature of the disease is such as to produce very rapid anæmia and wasting It is necessary to combat these results by the plentiful use of nitrogenous food—meat, fowls, eggs, rich broths, milk, etc.; if restricted to a milk diet these patients will very rapidly fail.

The character of the lesions gives the key to the most successful treatment, viz., consisting of thorough irrigation of the intestine, first with simple warm water for cleansing purposes; second, with an antiseptic solution for destroying the organisms and stimulating the ulcers to heal. For the latter purpose he has tried solutions of quinia, creolin, and silver nitrate—the latter has given the best results—quinia, in his experience, failing to accomplish any permanent good. While not attempting to explain the mode of action, large doses of bismuth subnitrate and salol seem to have had a distinct effect in controlling the excessive frequency of the stools. Salines also at times are beneficial, their mode of action probably consisting simply of a cleansing effect, in sweeping out irritants of various kinds.

Dr. West believed amœbic dysentery the most common form in Texas. The amœba frequently invades the liver and is a common cause of abscess of that organ.

The paper was discussed by Dr. Carmona and Dr. Mendizabel, of Mexico, and Dr. Osler, of Baltimore.

The latter said that the amœbic dysentery might be extremely severe, so that the patient might die of hemorrhage from the bowels. He had recently seen such a case. Dr. Osler found quinine injections very useful in the cases which were not too chronic. Abscess of the liver is not always due to this form of dysentery, but may occur with the other forms. He had found the disease very hard to cure permanently.

The Bacteriology of Dengue Fever, by Dr. J. W. McLoughlin, of Austin, Texas, was the second paper. He said: The paper was a review of the original investigations which he made in 1885, during the last epidemic of this disease which visited the Southern States of North America. To this was added, for the first time, photo-micrographic illustrations of the micrococcus which he then obtained from the blood of persons having dengue fever.

A detailed report of his investigations of dengue was read at the meeting of the American Medical Association held in St. Louis, in 1886, and was afterward published in the Journal of the Association. It was not his purpose now to recapitulate at any length the results of work done at that time, nor to add new facts, as he had had no opportunity since then of testing results by additional investigations; he desired simply to submit for examination some photo-micrographic illustrations of jelly cultures of the dengue micrococcus, which were made for him by Dr. William Gray, of the Army Medical Museum at Washington, D. C.

An inspection of the photo-micrographs herein reproduced will reveal group arrangements of the micrococcus that are distinctive of this micro-organism, and which, so far as he can learn, are not found in other pathogenic bacteria. He regarded this as a matter of importance, and, to a large extent, he rested the claim that this microbe is intimately, if not causatively, associated with dengue fever, upon the characteristic groupings of this micrococcus. But aside from the probabilities thus furnished of this being the specific coccus of dengue, its unique group-arrangements render this micro organism a matter of considerable biologic interest; these are clearly shown in the three photo micrographs here shown. An inspection of a specimen revealed several filaments which,

on closer attention, it will be seen, are composed of segments which contain a number of cocci, grouped around a central coccus of larger size, perhaps an arthrospore; segments and cocci are all embedded in a matrix-like substance, which is probably micro-protein, to form the filaments which, it is seen, are all of the same pattern.

The next photograph (Fig. 2) represents a different grouping of this coccus which occurs in the development cycle of its life history. Here the filaments are seen undergoing dissolution; while the segments, which have become separated, are spread out in circular-shaped masses and which form an irregular mosaic in the picture. A further separation of the cocci into irregular groupings, with a total disappearance of the filaments, is shown in the next picture (Fig. 3). Here the grouping resembles staphylococci, and, to a less extent, streptococci, in their arrangements.

Now, these three photo-micrographs, representing distinct and different group-forms of the same coccus—which, however, bear a relationship to each other—were obtained from the same mounted preparation of jelly culture; and as the same group-forms were constantly found in other mounts, the conclusion that they represent development-stages in the biological history of this micro-organism seems well taken. And, furthermore, as this grouping has never been observed in other pathogenic bacteria, and is characteristic and distinctive of the cultures of the micro-organism which he obtained from the blood of dengue-fever subjects, he feels justified in claiming that it is intimately, if not causatively, associated with this disease.

The cultures of dengue micrococci from which these photo-micrographs were obtained, were made by introducing into test-tubes of sterilized Miquel's lichen jelly the small quantity of blood from a dengue-fever subject that would adhere to the point of a sterilized platinum wire. Of course, all necessary precautions against the entrance of other microbes than those conveyed from the subject with the blood, were scrupulously taken. That his efforts in this direction were successful is testified by expert bacteriologists, who have pronounced the cultures thus obtained to be pure.

The tubes of sterilized jelly, after their inoculation with dengue blood, were kept at 100° F., in a culture oven, for periods of time varying from three to twenty days, and reinoculations, from one tube containing a culture to another containing only sterilized jelly, were made from time to time during a period of six months. He was fortunate in keeping the cultures pure during this entire time, and all the tubes which he examined, with a few exceptions only, contained pure cultures of the dengue micrococcus. These culture micro-organisms were readily stained by all the aniline dyes to which they were submitted, with the exception of the brown colors—vesuvin and Bismarck brown—which failed to have any selective action whatever; but he obtained the best results from methyl-violet, which was found to be of especial value in bringing out the cocci and segments of the filaments. When unstained these bodies—filaments—appear as continuous tubular bacilli with highly refractive granules distributed within their central cavities, and do not show either cocci or segments. But when the cocci which have been separated from the filamentous groupings are examined, they can be distinctly seen, without any staining whatever, as reddish-brown colored bodies in active commotion; the color is most distinct when the cocci are massed together in considerable numbers, less distinct when they are examined separately.

Blood of dengue fever was microscopically examined by various methods. For example: it was examined in the fluid state immediately after its removal from the veins. It was dried on cover-glasses, then flamed and submitted to various staining dyes and chemical agents. And, finally, blood was aspirated from the veins of a dengue patient into a series of glass bulbs blown upon a glass tube (Liebig's potash bulbs). The end of the tube nearest the arm of the donor was then closed by a blow-pipe (the other end having been previously closed by packing with sterilized cotton), and the apparatus was put into a culture oven at 100° F. The blood was thus made a culture medium for the growth of any bacteria it contained. At various periods of time a bulb was removed by the blow-pipe, and its contained blood was examined by the methods referred to.

This method of culture proved quite satisfactory, as it furnished a large number of cocci in a small quantity of blood; and he thinks this a valuable means to examine blood in acute infectious diseases for bacteria, especially when these are found only in inconsiderable numbers in fresh-drawn blood. In the instance under consideration the blood in the bulbs, removed at various times, was found swarming with micrococci. In a few instances he saw in this blood what appeared as filaments, but on this point he cannot be positive, owing to his inability to find a selective stain for blood preparations; that is, a stain which the cocci would hold after its removal, by washing or decolorizing agents, from the blood-cells. He is sure, however, that no filaments were ever found in fresh-drawn blood from dengue patients—about forty in number—whose blood he examined.

Blood taken from the culture bulbs, if examined in a fluid condition, and without staining or other reagent, contained what appeared to be innumerable pigment granules floating in the plasma; the cell elements of the blood were also seen, normal in size, shape, and numbers. But when cover-glass preparations of this blood were stained by Löffler's solution of methyl blue, or by first submitting them to sulphuric acid for a few seconds, then washing and floating them on Lugol's solution of iodine, that which first appeared as pigment granules is now seen to be cocci, variously grouped, and located both within the cells and plasma. He does not recollect to have seen cocci within the cells of fresh-drawn dengue blood, but this was constantly found in the blood from the bulbs. The difficulty which he encountered in fixing the stain in the cocci with a degree of permanency that would enable him to resist the washes required to decolorize the blood-cell, was a source of much annoyance, and interfered with his efforts to display the presence of the cocci in the blood, and their relation to its cell elements. In fact he succeeded with but a single aniline stain, and with this imperfectly, in accomplishing this result.

By floating cover-glass preparations of dengue blood on Löffler's methyl blue solution for twenty-four hours, at 100° F., the cocci were found to retain the blue color after this had been removed from the blood cells. This method of staining blood preparations was found out late in his work, when fresh dengue blood was no longer to be obtained, and was used only with the blood taken from the culture bulbs. In these preparations the cocci were found both within and without the blood cells, and, what is somewhat singular, they were not of uniform size; some were as large again as others, and often a central body of deeper color was seen surrounded by a halo of paler color, like a central coccus and surrounding capsule.

In place of this, he invites attention to a picture obtained by first applying sulphuric acid for a second or two to cover-glass preparations of blood from the culture bulbs, and then staining them with Lugol's solution of iodine. The appearances obtained by this method were well shown by a photograph prepared for him by Dr. R. Menger, of San Antonio, Texas.

Some remarkable results were obtained by applying glacial acetic acid to cover-glass preparations of freshly-drawn dengue blood. Several cover-glass preparations of fresh blood, taken from the last patient he saw having dengue fever, in 1885, were flamed, and then submitted to the action of glacial acetic acid. When these were examined with a dry one-sixth, or better, with a one-twelfth, oil emulsion, numerous ovoid cocci, of a yellow-brown color, were seen in the blood plasma. The blood-cells—which could be distinctly seen—were normal in appearance and numbers, and did not contain any of these ovoid bodies. Unfortunately, the number of pre-

parations of blood thus treated, which he examined, were too few, and all coming from the same individual, do not furnish sufficient evidence on which to base a positive opinion. But if these results are confirmed by future investigations they will be valuable for diagnostic purposes. The difference in shape and size between the cocci seen in these preparations and those obtained from jelly and blood cultures is due, he thinks, to the action of the acid on the capsule of the coccus.

In conclusion, he wishes to say that these investigations were made in 1885, before very little, if any, original work in bacteriology had been done in this country. All of the apparatus used by him was extemporized, and the work was done by a general practitioner, without technical training other than can be acquired by any educated physician who will give the subject careful investigation and study. He requests, therefore, that these facts be considered by those who would too closely criticise the imperfections of this work. He admits there are many, especially when viewed from the present advanced stand-point of bacteriology.

The paper was discussed by Drs. Cronyan, Gardiner, Medizabel, and West.

Culture of Anærobic Bacteria.—Dr. F. G. Novy, of Ann Arbor, Mich., then read the paper. The first part of this paper contained a brief résumé of the principles and methods employed in the culture of anærobic bacteria. The methods were described under five heads: 1. Exclusion of oxygen. 2. Exhaustion of air. 3. Absorption of oxygen. 4. Displacement of oxygen. 5. Cultures in the presence of air.

The second part was experimental, and included detailed descriptions of a convenient and very simple apparatus for the culture of anærobic bacteria either in vacuum or in an atmosphere of some indifferent gas. The apparatus, which was described, moreover, did away with the use of such special and expensive culture-tubes as those of Liborius, permits the making of large serial cultures, the use of various culture media, whether solid or liquid, and also enables streak cultures on agar and Esmarch roll-tube cultures to be made. The usual sealing in a flame was discarded and replaced by a more convenient procedure. The apparatus consisted of a jar so arranged that ordinary culture tubes being placed therein the air could be exhausted or replaced by other gases.

The culture media employed for the growth of anærobic bacteria are also discussed, and the value of peptone, glucose, and gelatine additions carefully pointed out. The addition of litmus was shown to possess some valuable properties. Pure cultures of anærobic bacteria can be readily obtained, even in the presence of air, with as much ease as ordinary ærobic cultures. The common anærobic bacteria can thus be cultivated without any special apparatus, and such cultures furthermore possess the advantage of retaining their vitality for a considerable length of time.

This was Dr. Novy's second paper:

A New Anærobic Bacillus of Malignant Œdema.—In several guinea-pigs which died after an injection of impure milk nuclein solution, a marked œdematous condition was observed, resembling, and even more pronounced, than that of malignant œdema. In the subcutaneous tissue, peritoneal exudate, heart blood, spleen, liver, etc., were found enormous numbers of a long, slender bacillus. This organism was found to be obligative anærobic in character, and pure cultures possessed marked infections and extremely toxic properties, producing death in from twelve to thirty-six or forty-eight hours, with the characteristic œdematous condition. White rats, white mice, rabbits, guinea-pigs, and pigeons, are all extremely sensitive.

The organs and tissues of animals that have died after inoculation with pure cultures contain very few germs, and often none can be found, showing that the normal body is not a very good soil for the growth of the germ. By injecting certain chemical substances and cultures of common non-pathogenic bacteria at the same time with the virulent germ, this natural resistance of the body is altered, and as a result the germ develops in enormous numbers throughout the body.

This new, highly pathogenic anærobic bacillus is motile, and the flagella can be readily demonstrated by Löffler's method. In some of the cover glass preparations made from animals colorless spirals can be observed. In cultures on certain media and under certain conditions are found similar spirals, which in reality are giant whips. These can be readily seen in hanging drops even with a dry objective. These abnormal flagella are exactly the same as those described by Löffler in connection with symptomatic anthrax, and their formation is probably due to involution changes.

The germ is readily stained by simple dyes and also by Gram's method. Spore formation has not been observed, but the germ itself is extremely resistant. It can be grown in vacuum, in hydrogen, carbonic acid, nitrogen, and even in illuminating gas.

There was no discussion of this paper.

Fourth Day, Friday, September 8th.

On motion by Dr. L. F. Bishop, of New York, seconded by Dr. M. Day, of Kansas, the following papers were read by title and ordered published in the Transactions: A paper on "Cold Steel as an Anti-rheumatic," by Dr. W. K. Vance, A.M., of Bristol, Tenn.; "Facts in Stethoscopic Percussion," by Dr. Henry Sewall, Ph.D., of Denver, Col.; "A Study of Some Cases of Chronic Diabetes," by Dr. N. S. Davis, Jr., of Chicago, Ill.; "A Case of Acromegaly in a Giantess," by Dr. Woods Hutchinson, of Des Moines, Ia.; "The Value of Rest as a Therapeutic Agent in Chronic Pulmonary Tuberculosis," by Dr. Karl von Ruck, B.S., of Asheville, N. C.; "Progressive Pernicious Anæmia," by Dr. Judson Daland, of Philadelphia, Pa.; "On the Occurrence of a Form of Chronic Bright's Disease, other than Typical Fibroid Kidney, without Albuminuria," by Dr. D. D. Stewart, of Philadelphia, Clinical Lecturer on Medicine, Jefferson Medical College; "Clinical Study of the Disease known as 'La Buba,'" by Drs. Luis Razotti y N. Guardia, Jr., of the University of Caracas; "Insanity in the Negro," by Dr. J. B. Da Lacerda, of Rio Janeiro; "The Cause of Yellow Fever," by Dr. J. B. Da Lacerda, of Rio Janeiro, Brazil; "A New Disease of the West Indies," by Dr. Cuthbert Bowen, of Barbadoes, West Indies; "Two Cases of Anæmia due to the Ankylostomo Duodenale," by Dr. J. B. Agnoli, of "Victor Manuel" Hospital, Lima, Peru; "The Nature of the Germicidal Constituent of Blood Serum," by Drs. Victor C. Vaughan and Charles T. McClintock; "Recent Experiences in Croupous Pneumonia, with Observations on Treatment by Subcutaneous Inspections of Saline Solutions," by Dr. R. F. Cunningham, of Birmingham, Ala.; "Cholera, its Diagnosis, Prognosis, and Treatment," by Dr. J. M. Hurley, of San Bernardino, Cal.; "Asiatic Cholera," by Major Dr. Santiago Hernandez, of the Spanish Army; "The Importance of Eliminating Pelvic Diseases in General Diagnosis," by Dr. Mary H. McLean, of St. Louis, Mo.; "The Need of Research in Preventive Medicine," by Dr. J. M. Postle, of Hinckly, Ill.; "Some American Ideas about Chronic Diarrhœa," by Dr. Ephraim Cutter, of New York City; "Tratamento medico del vomito negro," by Dr. Segundo Bellver Mateo, of Havana, Cuba; "Forced Respiration—Fell Method—A Plea for its General Adoption in Hospital and Naval Practice," by Dr. George E. Fell, of Buffalo, N. Y.

SECTION ON OBSTETRICS.

Third Day, Thursday, September 7th.

A Method of Performing Rapid Manual Dilatation of the Os Uteri, and its Advantages in the Treatment of Placenta Prævia.—Dr. Harris, of Paterson, claims that in most cases manual dilatation of the os uteri, from the introduction of index-finger to full hand, can, under

ether anæsthesia, be accomplished in about twenty minutes. This applies to any case of "cross birth" or "placenta prævia" which has reached seven months of utero gestation. In the seven successful cases of placenta treated in this manner by him (all the mothers recovering) the dilatation of the os from first finger to full hand was accomplished in an average time of nineteen and a fraction minutes. The shortest was sixteen minutes, the longest time twenty two minutes.

The average time for completion of labor (delivery of child and placenta) was twenty-five and one-eighth minutes, thus giving an average time for all cases, from introduction of index-finger to completion of delivery, of forty-one minutes. Five of the seven cases had not had a single labor-pain prior to the introduction of hand into the uterus and bringing down of one foot (the delivery of those five cases having been a purely elective operation).

Dr. Harris's method of effecting tonic strain on the os, strange as it may seem, is accomplished mainly by flexion of one or more of the fingers and extension of thumb, or the first finger, in a manner which exerts great force and does not fatigue the operator.

A full description of the manner of using the thumb and index finger, followed one by one by the other fingers, was given.

Dr. H. J. Garrigues, of New York, supposed the method described by Dr. Harris was new to most of those present, as it was to him, and he thought it would be very efficient in dilatation of the os, much more so than by the method of using the fingers by extension instead of by flexion. Manual dilatation and delivery was the only proper way of meeting placenta prævia, and was the method in New York.

Dr. R. A. Murray, of New York, gave some facts in the history of manual dilatation of the os and placenta prævia, and other conditions requiring rapid delivery, and spoke of the effect of this and aseptic measures in driving puerperal sepsis from the maternity institutions in New York. Rapid manual dilatation was employed only in placenta centralis, not in placenta lateralis. By means of it he had saved six children and all of the mothers in eight cases.

Drs. Upshur and Saunier made a few remarks.

Maternity Hospitals and Their Results.—Dr. Joseph Price, of Philadelphia, presented this paper. There was great hope in the fact that the impulse of the profession was away from and above old standards. We have learned the evil results of hurry; the interests of the mother and child are no longer to be sacrificed to the urgencies of private practice. It was not unsafe to predict that obstetrics will become a specialty, and in its ranks will be found the cleanest and most scientific men of the profession. The better statistics of maternities over those of private practice were due to the selection of the best men, those most advanced in the science of obstetrics, as medical managers of lying in institutions, their enforcement of rigid asepsis and exclusion of meddlesome midwifery. Too many of those going out from the schools to practise were ill-equipped for obstetrical work, and carried many risks to mothers and infants. Yet the lessons of both gynecology and obstetrics had come to remain with us. They taught that we have no right to tolerate either filth or blunder in our work. Old theories and beliefs had been gradually giving way before the assaults of our better facts, each age found fewer superstitions in medicine and surgery. The trustees of our schools and maternities held the highest trust, a trust which ruled over mother and offspring, a trust which ruled over every grade of life. But they did not always fulfil their trust with the best judgment. Teachers and managers should not be appointed on account of their pedigree, their family connections or wealth, but for their brains, knowledge of the subject, and energy in advancing the school. There should be no small amount of the mental and moral in the faculties of our great schools. The work, it should be remembered, could not be so well done but what it could be done better; with each death there would, and should, be a stronger demand for better obstetrical teaching and practice.

The Axis-traction Principle in Obstetrics.—Dr. Joseph Hoffman, of Philadelphia, read an abstract of his paper, and showed an axis-traction forceps for which was claimed certain advantages over others, especially that feature in others involved in the stiff traction rod. The traction in the instrument presented was exerted directly upon the middle of the fenestra, to which tapes were attached, one to each, these in turn attached to a rod with nearly a right-angle bend. The line of traction consequently was the hypotenuse. This arrangement resulted in certain important advantages: 1, Traction in the line of the axis, at first downward and backward, afterward downward and forward; 2, forceps permitted to rotate freely with the head; 3, no compression effect, only traction upon the head; 4, the forceps could be left on until the head was expelled through the vulva, and to advantage, for the traction as it reached the perineum was up over the symphysis, taking pressure from the distended perineum, and lessening the liability to rupture.

Forceps Delivery.—Dr. James Campbell, of Hartford, in this paper condemned the abuse of the forceps, while approving their use when really indicated.

Three marked examples of their abuse or neglect to use them when indicated were cited, and the author believed similar cases occurred frequently in every town and city. In one instance the doctor resorted to forceps in a normal case in order that he might keep another appointment, and the result was tears of the cervix and perineum. In another instance the forceps delivery lasted more than four hours, when intelligent use of the instrument would have extracted safely in little time. One doctor allowed the woman to remain in labor over two days, when forceps would have spared most of the suffering and saved life of mother and child.

The Use and Abuse of the Forceps.—Dr. W. Frank Holhaulen, of Philadelphia, read the paper, the title of which he said might have been a few practical questions concerning the forceps. Among those questions were: Are we justified in using the forceps for the sole purpose of economizing time? No. Are we justified in using them in normal labor in hyperæsthetic women? No. He would favor chloroform if the pain were too great. Should we apply them before the head is engaged in the superior strait? No, not so long as the head is movable, but rather perform version. Are we justified in using forceps in slow labors which otherwise are normal? He thought not, although the temptation might be great. Should we ever apply the forceps in the transverse diameter of the mother's pelvis? He thought not, except where the head was in the antero-posterior diameter. Are we justified in making traction, regardless of the natural curve through which the fœtus has to pass? He thought not. Is compression of the forceps justified beyond the degree necessary to retain the hold upon the head? He thought not. How long shall the head be allowed to remain against the perineum? This question was difficult to answer, but if the parts were rigid but moist, and the head made a little progress, one might wait an hour or two. Are oscillatory movements of the forceps during traction justifiable? Though condemed by some, he thought such oscillatory movements, when made with care, facilitated delivery. The several papers were discussed by Drs. Garrigues, Cortwright, and Joseph Price, who endorsed the remarks of Dr. Hoffman with regard to the traction of forceps presented; R. Wilson, F. Zárraga, of Mexico, who feared the forceps shown by Dr. Hoffman would slip from the child's head unless compression were made through the handles; R. L. Sibbett, Chestnut, Nelson, of Virginia, and Ayres, of New York.

Afternoon Session.

To Regulate Midwifery.—Dr. Root, chairman of the committee appointed Wednesday, read the resolutions which the committee had drawn up.

"*Resolved*, that the Section on Obstetrics of the Pan-American Medical Congress protests against the irregular practice of obstetrics by midwives, and, in view of the danger to the community incident thereto, recommends that the Boards of Health or licensing boards of the various states refuse to grant licenses to applicants to practise midwifery who have not received technical instruction and preliminary training after at least one year in competent schools and passed an examination in obstetrics equal to that required of the applicant for the degree of medicine; that copies of these resolutions be sent to licensing boards or Boards of Health of the several states." The resolutions were adopted without discussion.

The Influence of Surgery on Modern Obstetrics.—Dr. Thomas Opie, of Baltimore, in this paper referred to some of the more important epochs in obstetric science, the discovery and perfection of the forceps, etc., and made a plea for the more general application of the knowledge gained among obstetricians. One of the gravest duties of the attendant was to bring the head safely through the outlet, and he expressed his faith in the value of supporting the perineum. He warmly condemned the spreading custom of criminal abortion and pointed to possible complications requiring ultimate surgical interference when the mother refused to nurse her own child.

Symphyseotomy.—Dr. Henry J. Garrigues, of New York, read the paper. Symphyseotomy was invented and performed by the Frenchman Jean René Sigault in 1777. After having fallen into discredit everywhere else, it was kept alive in Italy, and was dying out there when Morisani revived it in 1866, but without finding imitators elsewhere, until in 1891 his pupil, Spinelli, demonstrated it to Pinard. Thus brought back to Paris, it has spread over the world with such rapidity that it has become impossible to keep accurate account of the statistics.

When the symphysis and subjective ligaments are cut, the limbs bent, and the iliac bones pulled apart, a separation of 7 cm. (two and three quarter inches) between the ends of the pubic bones is easily obtained without injury to the ilia sacral joints. The head enters into this gap, and all diameters of the pelvis are considerably increased. The distance between the centre of the promontory and the end of the pubic bones, at the safe distance of 7 cm. (two and three-quarter inches), gains 14 mm. (over one-half inch), the other diameters from 17–35 mm. (three quarters to one and one half inches).

Symphyseotomy is indicated in a flat pelvis with a true conjugate ranging between 67 and 88 mm. (two and five-eighths to three and one-half inches), but it is difficult below 7 cm. (two and three quarter inches). In a generally contracted pelvis the upper limit may be extended to 10 cm. (four inches), and we should cautiously approach the lower limit.

Other indications, for which it has been performed, are pelvic tumor, mento-posterior face presentations, if the chin cannot be rotated forward, occipito-posterior vertex presentation with impacted head; and it has been proposed in cases of absolute contraction of the pelvis (*i.e.*, below 5 cm.—two inches) with dead child, in order to facilitate craniotomy and embryotomy.

The sacro iliac articulations must be movable. There are two chief methods, the subcutaneous (Morisani's) and the open (Pinard's). The child may be left to be expelled by uterine contractions, or removed with forceps, or turned and extracted. Considerable lesions of the soft parts have occurred even in the hands of first-class operators. In many cases the hemorrhage has been profuse and sometimes difficult to check. Most children are born more or less asphyctic, and in some there has been fracture of the skull.

Symphyseotomy has come to stay and deserves a large place in the practice of skilful operators, but should not be attempted by the average accoucheur. In lying-in hospitals and private practice of specialists it should take the place of craniotomy on the living child and induction of premature labor, in which the infantile mortality is over forty-three per cent. Cæsarean section should be limited to cases that lie beyond the domain of symphyseotomy. Symphyseotomy has several times been successfully performed twice on the same woman.

Recent Surgical Advances and their Relation to Conservative Obstetrics.—Dr. W. Reynolds Wilson, of Philadelphia, read this paper. In view of the fact that the science of obstetrics is the most stable of medical sciences in which fixed mechanical laws largely determine both the event and the conduct of parturition, the influence of modern surgery in modifying obstetrical practice is unexpected. This influence is observed in the present treatment of abortion, ectopic gestation, dystocia, in contracted and deformed pelves, and septicæmia.

The operations which have become recognized obstetrical procedures in these conditions are: in abortion, curetting in order to remove every trace of decidual tissue, irrespective of symptoms of retention; in ectopic gestation, the removal of the gestation sac as soon as the diagnosis has been established, irrespective of the viability of the fœtus; in impeded labor, Cæsarean section and symphyseotomy; in septic infection, curetting and drainage by means of gauze; cœliotomy for peritonitis, and supravaginal hysterectomy for lymphatic infection of the mucosa.

Surgery deserves the lasting praise of the profession for the scientific treatment of tubal pregnancy, no surgical procedure being too radical for this condition, but of all these procedures the active treatment in abortion and in septicæmia and the substitution of symphyseotomy for the forms of treatment formerly recognized in dystocia from contracted pelvis, are to be questioned.

The conservative treatment with exact indications is illustrated in the five hundred cases from the records of the Philadelphia Lying in Charity, and deductions are drawn from these cases showing instances where surgical treatment in cases of abortion, septicæmia, and dystocia are replaced by expectant treatment, with results favorable to the latter method.

Dr. Noble, of Philadelphia, in discussing Dr. Garrigue's paper, gave preference to the subcutaneous section of the symphysis. In the case in which he performed it he deliberately let the time pass when premature delivery might have been practised, preferring symphyseotomy especially in the interests of the child.

Dr. Gutierrer approved Dr. Garrigue's paper.

SECTION ON GYNECOLOGY AND ABDOMINAL SURGERY.

First Day, Tuesday, September 5th.

Dr. L. S McMurtry, of Louisville, Ky., the presiding officer, made welcome all delegates of the Pan-American states, and advised that the interesting list of papers be entered upon at once.

The Intra-uterine Tampon was the title of a paper by Dr. Andrew F. Currier, of New York. He said that the vast experience in gynecology which has accumulated, particularly during the past fifteen years, has educated us to accept measures which would have been regarded as inexcusably rash in pre-antiseptic days. The freedom with which the curette is now used within the uterus is an illustration in point. The usefulness of instruments for the dilatation of the uterus has been generally appreciated only during the era in question, and the same is true concerning the principle of drainage in its application to the same organ. Dilatation, curettage, and drainage are the three principal foundation-stones upon which intra-uterine treatment may be said to rest. From the propriety of dilating the uterus to that of packing it with a tampon is a logical step. The vaginal tampon is an indirect and often unsatisfactory means of relieving uterine trouble. The intra-uterine tampon goes directly to the source of the trouble and has opened a new field in intra-uterine therapeutics. Sterilized gauze is the

material which offers the greatest number of advantages for such a tampon.

In the impregnated and puerperal uterus it may be used, 1, during the period of gestation; 2, during parturition; 3, post-partum, whether the labor occur at term or prior to it. In the unimpregnated uterus its use is for, 1, exploratory and operative purposes in connection with disease of the uterus and its appendages; 2, hemorrhage; 3, endometritis; 4, stenosis; 5, accumulations within the tubes.

Dr. Maury, of Memphis, led the discussion that followed, asserting that we are indebted more to the use of the uterine tampon in the treatment of inflammatory conditions of the uterus, especially septic endometritis following labor, than to all other procedures.

Dr. Massey, of Philadelphia, would term the introduction of gauze in certain cases of catarrhal endometritis, and in stenosis, a plugging rather than a draining. Its apparent usefulness must be explained upon the ground of its being a counter-irritant; and the cause of the unfavorable results that had led its exponents to advise caution was not far to seek. For the hemorrhage and endometritis of a myomatous uterus he preferred galvanism by the intra-uterine electrode.

Dr. Joseph Tabor Johnson, of Washington, commended the paper, and like the author had been surprised at the amount necessary to fill the relaxed post-partum uterus. When the gauze at hand was limited, use might be made of it as an envelope into which strictly clean napkins or handkerchiefs might be thrust. In certain favorable cases it will replace cœliotomy. In the flooding of abortion, tamponing the cervical canal is rational treatment.

Dr. Cushing, of Boston, considered dilatation, curettage, and irrigation the essential factors in treatment of stenosis, and valued neither the gauze of Polk nor the stem of Wylie. In a series of curettements he had packed in every other case, and the result was no better where it was employed.

Dr. Van der Veer, of Albany, considered plugging an unfortunate term, and emphasized the capillary attraction properties of the gauze.

Dr. Carsons, of Detroit, thought there was danger of the intra uterine tampon becoming a fad. Undiagnosed distended tubes would be ruptured in the performance of the operation by the general practitioner. If any drainage were needed he preferred the glass, rubber, or silver stem.

Dr. Currier, in closing, would not recommend the tampon as a cure-all, but predicted a wide field of employment.

Treatment of Extra-uterine Pregnancy after the Viability of the Child, with a Report of Two Cases, was the title of a paper next read by Dr. Joseph Tabor Johnson, of Washington. Operation should be immediate upon diagnosis. The sac should be removed with the fœtus, if possible. In Lusk's case the placenta was removed, and the packing of the site with gauze controlled the hemorrhage.

Martin had ligated the vessels under the placenta and at the side of the uterus. Eastman removed the placenta in a similar way.

The first case was septic at the time of operation and the sac could not be removed. An early diagnosis would have saved the patient.

In the second case rupture had taken place into the broad ligament. Gestation had continued until the twelfth month. Diagnosis was exact, the placenta was not extensively adherent, and was removed with the ligature of a single vessel. Recovery good.

Dr. Price, of Philadelphia, in opening the discussion, stated that Dr. William Baynam, a Virginian, operated successfully for ectopic pregnancy in 1790, and again nine years later, but it remained for Mr. Tait to establish the procedure. Extensively engrafted placenta cannot be removed. Operation is demanded as soon as ectopic pregnancy is discovered. Electricity has no place in this discussion.

Dr. Massey, of Boston, cited two cases in which electricity had been employed. In the first, absorption followed death of the fœtus. In the second, a subsequent operation showed that absorption had begun, and that recovery would have followed without surgical intervention. He would employ the powerful electric current alone in the first three or four months of gestation, and later it should effect death of fœtus before an operation was attempted.

Dr. Stone, of Washington, related a case that shed a cast of the uterus at the fifth month. Here one could merely stitch the sac to peritoneum, evacuate the fœtus and bloody fluid, and leave the placenta *in situ*. Recovery followed.

Dr. Carsons, of Detroit, believed placenta could not always be removed. His knowledge of cases treated by electricity led him to condemn the treatment.

Dr. Price, in answer to a question of Dr. Massey, replied that he had had eighty-six cases of ectopic pregnancy with but three deaths.

Dr. Johnson briefly reviewed the discussion.

Dr. Burneys, of St. Louis, from an experience that embraced over one thousand laparotomies, declared in favor of attacking pus-tubes through the vagina, and attributed condemnation of the Péan-Segond operation to a misconception of its technique. So much of the lower segment of the uterus should be removed as permitted free removal of the abscess walls.

Dr. Carston, of Detroit, had given up treatment of diseased appendages through the vagina. It is impossible thus to obtain a free field of action, and some tubal or ovarian tissue is thus inevitably left to be a source of mischief. With the Trendelenburg position and approved methods of operating, one is enabled to remove the worst forms of pyo-salpingitis by cœliotomy.

Dr. Johnson said that while the paper had dwelt most exhaustively upon the pathology, it had also touched upon the treatment of pelvic abscess. He, too, thought poorly of the Segond method, as he had never seen a perfect cure of salpingitis attacked through the vagina. Draining need often be continued, and perfect results do not occur.

Dr. Noble was very glad to hear from Dr. Maury that abscess in the broad ligament is possible. He had himself reported six cases of cellular abscess, each following confinement, in none of which were the tubes affected, as established by cœliotomy. The pus was in each case evacuated by incision along Poupart's ligament. The cases were not well received, as in Philadelphia abscess in the broad ligament is a heresy. In some cases where he had persisted in removing the sac, a more fortunate result might have followed had he been content merely to drain.

Dr. Maury, in concluding, said it was possible to take out all abscess walls, but often the patient's life was best subserved by the slighter operation.

SECTION IN LARYNGOLOGY AND RHINOLOGY.

Second Day, Wednesday, September 6th — Afternoon Session.

A Case of Angioma of the Nasal Septum.—The paper was read by Dr. F. C. Cobb, of Boston. The patient, a girl, fifteen years of age, was examined at the Massachusetts Hospital in October, 1892. She complained of obstruction of, and bleeding from, the right nostril, with a duration of six months. There had been no sneezing, and only occasionally a yellow, thick discharge from that nostril. Her general condition was anæmic; she was subject to headache, and exhausted by slight exertion. Examination showed a small growth attached by a thin pedicle inserted into the septum of the right nostril, above the end of the lower turbinated bone, near the junction of the skin and mucous membrane. The growth was soft, its base dotted with a few small blood-clots. It moved backward and forward with respiration, but did

not pulsate. The right nostril was slightly atrophic; otherwise the upper air-passages were normal. The growth was removed, with very slight hemorrhage, with the aid of the Hooper snare and écraseur. The base was not cauterized, and the site was completely healed in a few days. In June, 1893, she reported that there had been no recurrence.

The diagnosis, made by the microscopist, was "cavernous angioma;" nineteen such cases have been reported, but in seven no microscopical examination was made. The diagnosis is therefore open to question; five contained myxomatous tissue, and were not therefore pure angiomata.

With regard to symptoms, the only two of importance are hemorrhage from, and occlusion of, one nostril. Out of seven thousand four hundred and twenty-nine cases at the Massachusetts General Hospital no similar case has been reported. Pure angioma may degenerate into malignancy. Careful microscopical examination alone can insure positive accuracy of diagnosis. In regard to treatment, all authorities agree upon the cold snare, used slowly, as the safest method of removal. In this particular case the slight hemorrhage was due to the thinness of the pedicle.

Dr. John W. Mackenzie, of Baltimore, had seen one case during the past year. The growth had been removed with the cold snare by one of his assistants. Removal was somewhat rapid, and there was considerable hemorrhage. He was surprised that anatomists still continued to neglect to properly describe the nasal mucous membrane. It contained a large net-work of cavernous sinuses. These have been mistaken for true angioma, while in reality nothing but a transitional stage between simple inflammatory and true hypertrophic rhinitis.

There was also another condition, viz., a pendulous state of the turbinated bodies, which might even protrude from the nostril and be mistaken for true angioma.

Report of a Case of Myxo-sarcoma of the Nasal Cavity.—Paper by C. W. Richardson, M.D., Washington, D. C. The interesting features in the case were numerous. The development of the growth, as noticed by the parents, was from early infancy. The age of the child at the time of operative interference was only four years and nine months. The enormous size of growth, filling out, as it did, the nasal and pharyngeal cavities. The complete absence of hemorrhage previous to, and the small amount at, the first removal of the growth. The rapid reproduction of growth—it filling out the left nasal cavity within four days after a most searching and thorough removal. From a pathological point of view it presents an interesting feature in the presence of single fibres of striated muscular tissues here and there disseminated throughout the growth. The growth was first removed by snare, but on its rapid reproduction a more radical procedure was adopted. The second operation was that of Billroth's for resection of the superior maxilla. Recovery was complete. Recurrent followed in four months in the pharynx and lymphatic glands of the neck. Result, death.

Sarcoma of the Naso-pharynx.—This was the title of a paper read by Dr. James E. Logan, of Kansas City. His patient was a man aged forty-four and a school teacher. At forty he had typhoid fever. Shortly after recovery he noticed a fulness of the throat, with considerable salivation. A tumor was found projecting into the pharynx. It was removed by operation, being regarded as a fibroid. There was a temporary improvement in the patient's health, but he soon lost appetite, became emaciated, and his former symptoms soon returned, with pain referable principally to the left ear. A diagnosis was now made of sarcoma. The growth increased so rapidly that operation was again deemed necessary. No less than nine operations were undergone, owing to recurrences of the mass.

When first seen by the reader of the paper he had a tumor twice as large as a partridge egg, situated partly on the roof of the pharynx and extending down a quarter of an inch along the posterior pharyngeal wall. It appeared lobulated and with a large base. The patient's condition was much below par. Considerable pain was felt in the ear and the back of the head. Digital examination provoked profuse hemorrhage.

The soft palate was tied back, a ten per cent. cocaine solution applied, and the growth divided into three sections with the cautery. One section was removed with the cautery knife, with but little hemorrhage; persulphate of iron was applied to the base. In a week the remaining sections had greatly shrunk and were removed as above. Microscopical examination showed it to be a round-celled sarcoma. Twenty such cases have been reported, with but one previous permanent recovery. In operating on these cases the gentlest means possible should be employed and all irritation of surrounding structures avoided.

These two papers were discussed by Dr. Ingalls, of Chicago, who related cases of intra-nasal tumors occurring in his own practice.

Local and General Treatment of Hay Fever.—This was the title of a discussion opened by Dr. D. Bryson Delavan, of New York.

Dr. Price-Brown, of Toronto, had himself suffered from the malady. He discovered sensitive areas in his own nostrils, which he cauterized. Afterward he removed a portion of his own uvula, which seemed to be the starting-point of reflex disturbance. Alumnol solutions had relieved one attack. He gave his patients weak cocaine solutions, but always dispensed them himself, and followed it up with menthol in albolene, five to twenty grains to the ounce.

Dr. J. O. Roe, of Rochester, had found a local intra-nasal lesion in every case of hay fever. He doubted the existence of the so-called general "neurotic" cases. Free nasal passages by no means necessarily meant healthy mucous membrane. There is or has been at some time intra-nasal pressure, and its removal is necessary for successful treatment. Nasal trouble may set up lesions in other parts, which persist after the primal cause is taken away. He regards the cautery as good only in vascular turgescence. Only the point of a projecting turbinated, giving pressure, should be taken off, and never the entire bone.

Dr. S. S. Koser, of Williamsport, Pa., finds terebene internally of service. Also, as a sedative measure, inhalations of carbolic acid and camphor in chloroform. We should always palliate before we operate. He chips the bone, as he does not regard the cautery permanent enough in its effects.

Dr. James E. Logan had had an experience practically identical with that of Dr. Roe. He used the cautery before the paroxysm, and gives pills of nitrite of sodium with camphor internally, for six or eight weeks after the attack is over.

Dr. J. H. Bryan, of Washington, D. C., thought that there must be two different conditions comprised under the term hay fever. Otherwise we would not find such diametrically opposed views as to its underlying pathology. He believed that it was impossible to permanently relieve the so-called "neurotic" cases.

Dr. E. Fletcher Ingalls, of Chicago, uses the cautery two or three weeks before the attack, so as to have healing complete before its onset. He employs it superficially, like a blister, so as to avoid the formation of cicatricial tissue. Internally he gives phosphate of brucia, camphor, hyoscyamus, quinine, etc., beginning one week before the attack.

Dr. John N. Mackenzie was glad that no one had spoken of the "pollen" theory as to the cause of the malady. It had been, in his opinion, a bar to the proper conception of the disease. He stated that he sees cases where there is no lesion in the respiratory tract in the intervals between the attacks. Pressure irritation he believes more liable to produce atrophy than hypertrophy. The various forms of rhinitis, hyperæsthetic, vaso-motor, etc., should all be classified under one heading. He employs nerve tonics, such as quinine, phosphide of zinc,

and nux, before meals, with Fowler's or Donovan's solution of arsenic after meals. Such a treatment will often clear up mild cases. If disease occurs in any part of the respiratory tract, it should of course be removed. The cautery should be applied to any sensitive areas.

OUR LONDON LETTER.

(From our Special Correspondent.)

STUDENTS' NUMBERS—THE WANING VACATION—CHANGES IN HOSPITALS AND SCHOOLS—THE NURSING QUESTION AT THE LONDON HOSPITAL—APPEAL OF THE NURSES TO THE PUBLIC—POSITION OF THE COMMITTEE—REFORM OF NURSING ARRANGEMENTS NEEDED IN MANY HOSPITALS—SMALL-POX AND THE SALVATION ARMY—CHOLERA—BACTERIOLOGICAL DIAGNOSIS—CHOLERA IN LONDON—BACTERIOLOGICAL CONFIRMATION—CHOLERA AT THE HUMBER PORTS—ASYLUMS AS SPHERES OF MEDICAL EDUCATION—COMMITTEE ON DEATH CERTIFICATION—REPORT OF LOCAL GOVERNMENT BOARD—CROUP AND DIPHTHERIA—KLEIN AND SIDNEY MARTIN—INFECTIVE ENDOCARDITIS—ANTHRAX—ANTAGONISMS OF MICROBES—DIFFERENCES OF SUSCEPTIBILITY—ACTION ON PUS—ANÆSTHETISTS—ROYAL COMMISSION ON OPIUM.

LONDON, September 2, 1893.

To-day the medical journals publish their "students'" numbers. This fact is a reminder of the rapid approach of the winter session and the termination of the long vacation. Some of my friends are already back from their holidays, but more remain a week or two longer away, while the favored few will not return until the end of the month just begun.

The contents of these "students'" numbers are a dreary repetition of official regulations of the teaching and examining bodies. There is very little effort to digest the information, and perhaps it would be hardly worth while; for the major part of the double number—the *farrago libelli*—consists of advertisements obtained by special canvass, under the promise of extra circulation among students and parents and guardians. I wonder if any parent ever waited for a students' number to decide on the career his son should commence the next month? Still advertisers walk into the net thus openly spread for them.

A great many changes in the *personnel* of our chief hospitals and schools will be noticed when the new session begins. The tale of death in the ranks is already known, but other changes of staff and shiftings of professorships will in some cases give an air of strangeness to those familiar with the old order. The list of changes is too long to give, even if restricted to the more important ones.

This is the "silly season" when the importance of "big gooseberries" is recognized in the provincial, and of grievances or scandals in the metropolitan papers. Hospital scandals are a delight to some editors, and the grievances of nurses to others. Our largest hospital—the London—has again and again been attacked, and just now the *Pall Mall Gazette* has opened its columns to the London Hospital nurses. Many will be tempted to think that such repeated outpourings of smoke must prove there is a smothered fire somewhere, and I can assure them that the deduction is just. It is, however, sad that so noble an institution as our greatest hospital can hardly escape injury by the barest statement of defects or of mismanagement. The hospital, though so big and so necessary to the locality in which it stands, is poor and always in debt. Just now a fresh effort to raise funds is to be made, and there comes this damper. Most of the complaints of nurses which have been published resolve themselves into charges of injustice. They would never have been heard of but for the pusillanimity or blindness of the committee, which seems to be bereft of all sense of judicial impartiality. I will instance one example from the *Pall Mall*. A sister applies for leave of absence after illness, and is called upon by the matron to resign. On her refusal the matron accuses her to the committee of breach of discipline and misconduct. Disproving the accusation, the committee nevertheless require her to resign, "as it would be a breach of discipline for her to remain after what had happened." So the injustice of the matron is not corrected by the committee, and her shackles are fixed the firmer on her subjects. Another nurse was called upon to resign on refusing to report certain insinuations against the sister above named. This nurse resigned, and in reply to her father's demand for explanations, the chairman actually wrote that she "had been accused of no fault, and if at any time she should require a testimonial from the London Hospital, she would receive a first-class reference; but that nothing further could be done in the matter, as the authority of the matron must be upheld." This is the root of the whole matter. The nursing is committed to the matron, who is an irresponsible autocrat. An appeal to the committee is useless when that committee refuses judicial functions by its foregone conclusion that the "authority of the matron must be upheld." It is no use trying to conceal the matter any longer—the public want to know why a number of charitable gentlemen should be allowed to establish a despotism untempered by responsibility? By what fascination does the matron hypnotize these gentlemen, and compel them, instead of investigating, to repeat "the authority of the matron must be upheld?" The committee has to pass many details, and has little time to examine them. The natural result is to trust them to heads of departments, but it is their obvious duty to review the decisions of their servants and to prevent oppression. In the present case the committee are responsible to the public, and for the sake of the great work carried out in the hospital they ought to abandon their habit of supercilious concealment of facts, and their affectation of irresponsibility for the decisions of themselves and their servants.

I have dwelt on this case because an appeal to public opinion is being made, and because it is a sample of what is going on in other hospitals. No one is fit to be trusted with absolute despotic power—least of all a woman over a number of her own sex. Faults, no doubt, there may be on both sides, but the great defect is in the system which makes one an irresponsible tyrant and consigns the others to submission or deception, the natural resort of slaves. Reform of the nursing department is needed in a number of our best institutions, and the reform should begin at the top.

I regret to have to report the death of another eminent physician, well known to me, and whose name—Dr. Graily Hewitt—must be familiar to your readers. He was for many years obstetric physician to University College Hospital, and professor of this branch in the college, and when he retired from these offices a few years ago, was elected consulting physician and emeritus professor. His work on "Diseases of Women" reached a fourth edition, and was highly esteemed by many of his pupils and others. He was a past president of the Obstetrical Society, and a member of numerous learned institutions. His compeers will recollect the great importance he attached to mechanical considerations in uterine therapeutics.

I mentioned in a former letter the danger of the spread of small-pox through the Salvation Army shelters, which are not registered as common lodging-houses, and accordingly not open to sanitary inspection. With all the good work done by these charitable shelters, it is a pity to see them become foci of contagion, and the managers must be blind not to avail themselves of the advice of the medical officers of health. One of the so-called "officers" of the Army, a "Captain" Coldough, has contracted the disease in his attendance on a sufferer that he took in and "looked after like a brother." This event

should rouse his superior "officers" to a sense of their duty and responsibility.

I have previously mentioned cases of suspected cholera. One of them was referred to Dr. Klein for bacteriological diagnosis, and he reports that it was of Asiatic type. Forthwith the port where it occurred is declared infected, and the announcement thus made that the disease has set a foot on our shore, while every effort is made to prevent it securing this feeble foothold. Perhaps if other countries had dealt as fairly this would not have happened. All our sanitary officers are on the *qui vive* and still hopeful. It is a curious coincidence that Dr. Klein should have had to make the bacteriological investigation. When Koch announced his discovery of the comma bacillus, Dr. Klein refused to acknowledge its importance, and undertook to drink a fluid containing the accused bacilli. How far does he now rely on their presence as a test, or by what other bacteriological signs does he pronounce a case to be Asiatic cholera?

London, September 9, 1893.

Last week I was able to inform you that cholera had effected an entrance at our Humber ports. To day I have to report that the disease has appeared in London. Last evening Dr. Thorne Thorne issued an official statement on the invasion. This shows that on September 7th there was another death at Grimsby, and thirteen new cases, that fifty persons were under treatment, including cases of diarrhœa. Cleethorpe, a suburb of Grimsby, has also had cases, and further deaths have occurred at Hull. The invasion of London cannot be well accounted for. A cleaner at the House of Commons who had no known connection with infection was suddenly struck down and the bacteriological examination offers no difference from Asiatic cholera. A case occurred at Islington, a northern locality of the metropolis, and was conveyed to St. Bartholomew's Hospital. Another case appeared in Marylebone (west central district). A lad of twelve died in some model dwellings near the Edgeware Road (western district), after seven or eight hours of choleraic diarrhœa, but the bacteriological examination is not yet complete. Early yesterday two vessels from Bremen arrived in the Thames with seventy-four and sixty-two passengers respectively. Their addresses were taken, or they were detained and will be watched until the danger has passed. Yesterday there were eleven cases in hospital at Grimsby, two of which were admitted the previous day; no death. At Hull no fresh case was admitted, and it is hoped the outbreak is at an end there. From other parts of the country scattered cases of suspected cholera are reported this morning and will be fully investigated by the local government board. We have nothing like panic in the country, and the sanitary authorities are awake. There is a certain amount of perturbation in some quarters, but perhaps less than on former occasions. There is a recognition of the gravity of the fact that cases of unquestionable cholera have appeared in different districts of the metropolis, but relying on the activity of the health officers there seems a general confidence that we shall escape a severe visitation.

The London County Council propose to open their large asylums for medical teaching. This will be a great gain to medical education as well as to the public. A knowledge of mental disease is of great importance to every practitioner, and the means of requiring such knowledge ought to be at the disposal of all students. Hitherto such opportunities have been very restricted, and the immense asylums of the London County Council afford so ample a field for instruction that I hope the scheme may be carried out.

I hear, too, that the Council contemplates engaging the services of a skilled pathologist, so that medical men cannot complain that the interests of medical science are altogether neglected by the metropolitan authority.

The report of the Select Committee on Death Certification has been laid on the table of the House of Commons. It is an elaborate document and will, perhaps, lead to early legislation. It recommends that a certificate of death signed by a registered practitioner, or when an inquest has been held by the coroner, should be a condition precedent of registration in every case. This is most important, as it is well known that many deaths have been registered without this guarantee. Moreover, all certificates in the prescribed form are to be sent direct to the registrar instead of being entrusted to the friends of the deceased. This will, in many cases, relieve the medical man of some anxiety, and probably tend to greater accuracy in the returns, as it is at times very unpleasant to state for the inspection of friends the full cause of death and so add to their distress. These certificates must be regarded as official documents, and not as details for the inspection of the curious, and are assuredly not properly handed about among friends and relatives. I do not observe that it is proposed to pay for them, and yet medical men should certainly be remunerated for the trouble of providing the state with such important statistics. No one would venture to propose that solicitors should be compelled to furnish certificates of anything gratuitously, but doctors seem to be expected to thrive on unpaid labor.

In the new report of the medical officers of the Local Government Board, to which I have previously referred, Dr. Klein and Dr. Sidney Martin sum up the pathology of diphtheria in a manner that has produced a decided opinion in many circles that we may regard the nature of the disease as now established. The true cause is announced to be the bacillus of Klebs and Loeffler. Dr. Klein says scarlatinal diphtheria is not the true disease—a conclusion which will not be disputed by many clinicians. He also holds that membranous croup when concurrent with faucial diphtheria is true diphtheria, but when not thus associated it may be or may not. What is this but a return to the old clinical distinction between croup and diphtheria, with a shifting of the argument from the bedside to the microscope? If a bacteriological distinction between the various cases can be established with such certainty, surely those clinicians who always maintained the non-identity of the diseases must be credited with as much insight as those who have so loudly asserted their identity.

Dr. Martin seems to have fairly traced the manner in which the bacillus acts. His research confirms and extends the work of Roux and Yersin, and of Brieger and Fraenkel. But he works on a different plan. They investigated the products of the bacillus; he the blood and tissues of those who died of diphtheria. Oertel and others have gone a long way to show that the poison of diphtheria circulating in the blood breaks up proteid in the tissues in a somewhat similar manner to the action of pepsin in indigestion. Dr. Sidney Martin shows that the albumoses and an organic acid formed by the bacillus are the deleterious agents, causing the fever, the prostration, and the paralysis. These conclusions had been reached by him in 1892 and were stated in his Gulstonian Lectures. They are now given in a revised and complete form illustrated by photographs and micro-photographs.

Dr. Martin also contributes an account of an investigation on defective endocarditis on the same lines. He concludes that in this disease and in anthrax the respective chemical products are specific, separable to some extent chemically, but more completely by physiological action. The spleen seems to be the chief locality of the fermentative changes. Here the blood as it passes through the spaces must be comparatively stagnant, and here, therefore, micro-organisms or ferments would be more active.

Dr. Klein has continued his research on the antagonism of different microbes. Experiments on vaccinia and erysipelas were begun, but dropped, as it was found calves were not susceptible of erysipelas. Some evidence is offered of an antagonism between the bacillus of grouse disease and that of malignant œdema. In guinea-pigs tubercle was delayed by injecting sterilized cultures of bacillus pyocyaneus.

Dr. Hamer experimented on the chemistry of susceptibility. He found that saliva restrained the growth of bacillus subtilis and did not lose this power by boiling. Pancreatic juice did not possess the same power. Dr. F. W. Andrewes found a great difference in the power of different organisms to develop in pus. Thus the bacillus diphtheriæ grew in pus, but the bacillus anthracis would not grow and soon died.

The anæsthetists have started a society all to themselves, to begin with a dinner. It must be doubtful to many whether the multiplication of small societies can be useful. Anæsthesia is not a tabooed subject at any general medical association. A society consisting only of anæsthetists to recognized hospitals threatens to withdraw the intensity in anæsthetics of many who are from time to time obliged to assist their neighbors by undertaking the administration of these agents.

The Royal Commission on the Indian Opium Trade has begun its sittings.

OUR BERLIN LETTER.

(From our Special Correspondent.)

NATURE'S SUBSTITUTION OF A VOCAL APPARATUS—THE SPEAKER WITHOUT A LARYNX—ENDOCARDITIS GONORRHOICA—GONOCOCCI IN A NEW RÔLE—REPORT ON NITRATE POISONINGS SIMULATING ASIATIC CHOLERA DEATHS—ABOUT DULCIN, THE NEW REMEDY FOR DIABETES.

BERLIN, August, 1893.

WITHIN the last few weeks a very rare case has attracted the attention of our profession. A man who, although having his whole larynx extirpated, is able to speak clearly, loud, and correctly. The case belongs to Dr. Hans Schmidt, of Stettin, who demonstrated the case in the medical society recently.

Pal——, aged forty-five, male, was operated upon seven years ago, for a probable carcinoma of the larynx. The whole larynx and its immediate surroundings were removed. The œsophagus was opened twice, leaving œsophageal fistulæ which interfered materially with the after-treatment. The patient was plied with bougies daily, in order to keep up the relationship between the mouth and œsophagus on the one hand, and the air-passages on the other hand. Although the greatest care was taken, the patient grew steadily worse, and after begging to be released, was sent to his home to die, as it was believed. Dr. Schmidt was greatly surprised to find the patient who could not utter a word when released, suddenly reappear in perfect health, and speaking fluently. The conditions were the following: The air-passage ended where tracheal fistula existed, in which there was a cannula. From this fistula, in an upward direction toward the œsophagus, there was no connection. A careful examination determined the following conditions: A powerful tongue, strong palatine arches, large hypertrophic tonsils, and a pharyngeal wall which was tilted forward. With a head-mirror looking downward was discovered a round opening which showed the entrance to the œsophagus, and which appeared to enlarge downward, like a crater. This opening changed its form. It assumed an oval shape, both sides seemed to lie together when the patient intonated, and from behind a small partition could be seen during intonation; besides, small air-bubbles could be noticed rising and bursting.

It was of the greatest interest to discover how this patient phonated. Laudois and Strübing examined him and expressed the opinion that the voice was formed in that space which was regarded as a vacuum. In the latter space the air was taken in and forced out. In this space, and in a second space lower down toward the œsophagus, sound was formed, which was utilized in the formation of vowels and consonants. The latter deductions seem different from Professor B. Fraenkel's examinations. Professor Fraenkel found that the patient was able to intonate as well when his tongue protruded as when it did not. The tongue can therefore be excluded from sound formation. Fraenkel further believes that sound formation is the result of a three-cornered slit (lip-shaped) in the œsophagus. Where does the patient obtain the air necessary for the production of sound? Fraenkel believes that the patient, prior to phonation, by a suction process draws air into the œsophagus, then the glottis of the œsophagus narrows itself, and now in an expiratory manner presses the air out in order that the compensatory vocal organ shall vibrate. This demonstration showed a cure—by nature—which we physicians can envy. Here is the "vis medicatrix naturæ" in her grandest form.

A very interesting subject is a case by Professor Leyden, "Malignant Endocarditis." Leyden was able in the polypoid vegetations of the aorta and mitral valve, as also in the endocardium, to demonstrate Neisser's gonococci. The patient had gonorrhœa, epididimitis, and gonorrhœal rheumatism, was put into a surgical ward, and transferred to Leyden's ward. Formerly we supposed a relationship existing between gonorrhœa and endocarditis, caused by streptococci. After the examinations by Leyden, however, the direct transmission of gonococci in the blood is proven. Leyden found in the above-named vegetations only gonococci (Neisser). The proof for the latter micro-organism being, 1st, its form, 2d, its position (peculiar) in the pus-cells, 3d, through its staining and loss of stain by Gram's method. In future endocarditis will receive more bacteriological attention than heretofore.

Cholera is still the subject of study. Recently Emmerich and Tinboi announced as a result of their investigations, that cholera is due to nitrite poisoning. Emmerich bases his results on: 1. The similarity of the symptoms, and the pathological anatomical changes in both cholera and nitric poisons in animals and human beings. 2. The spectroscopic results of methæmoglobin in the blood of guinea-pigs which died of cholera. Besides severe forms of collapse, vomiting, and diarrhœa were noticeable in poisoning with nitric acid. The animals also showed that after taking nitrites, collapse occurred with vomiting, diarrhœa, subnormal temperature, injection, and inflammation of the intestine. These experiments were followed by Dr. S. Klemperer, in Berlin, assistant to Leyden's clinic. He found that when cholera cultures were heated to 55° C., they lost their nitrite properties, and if then injected into animals (guinea-pigs) they still invariably died of cholera intoxication. Klemperer further found that it is an axiom that a chemical substance, which is the specific poison of a pathogenic bacterium, must render animals immune by injections of some.

It was found that, although different quantities of kalium nitrite were injected into animals, that, after inoculations with cholera cultures (agar washings), the animals invariably died. Klemperer could not verify the presence of methæmoglobin in the blood.

Saccharin has received a new competitor in dulcin. The latter is made from phenitiolin and urea. From a chemist's point it is a phenetolcarbomid, derived from benzol, as saccharine is. It is 200 to 250 times as sweet as cane sugar, according to investigations by Professor Ewald. It is harmless. The same was reported by Professor Kassel. Tablets containing 0.20 and 0.025 gm., equivalent to 5 gm. sugar, are made. It is applicable chiefly in diabetes. Whether dulcin contains antifermentative qualities like saccharin, remains to be seen.

Two Kinds of Prophylaxis.—There is a great deal of trouble in this world which arises from jumping at conclusions and taking things for granted. A case of this kind occurred in Detroit a few days ago when a little girl rushed in from school and said that the teacher said she must be baptized. The parents held their own views on the subject of baptism, and at once resented the interference of the teacher; but on investigation it was found that the child had made a mistake. The teacher had said "vaccinated" instead of baptized.

New Instruments.

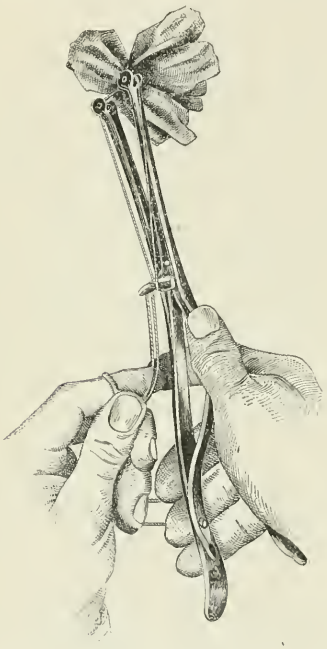
A NEW INSTRUMENT FOR TIGHTENING LIGATURES.

By EDWARD A. AYERS, M.D.,

NEW YORK,

PROFESSOR OF OBSTETRICS NEW YORK POLYCLINIC, OBSTETRICIAN MOTHERS' AND BABIES' HOSPITAL, THE CENTRAL HOSPITAL, BROOKLYN, ETC.

THE accompanying cut shows an instrument designed to act as a ligature tightener. Its special applicability is found in operations in deep cavities, such as abdominal or vaginal hysterectomies, where thick pedicles must be tied, and where the fingers lack the power to draw the ligatures tight enough. Slipping of ligatures following operations for the removal of fibroids, ovarian tumors, extra-uterine growths, diseased uteri, etc., followed by fatal hemorrhage, have been needlessly frequent. As a



medical student, in 1879, I saw a patient die in half an hour after a vaginal hysterectomy, from hemorrhage resulting from a poorly tied ligature. I made the post-mortem. Since then I have known of quite a number of such "accidents."

The Trendelenburg-Meyer position has been looked to to lessen the number of such accidents, and may safely be said to have done so. This instrument will add further accuracy in a life and death part of the work, and so bespeaks careful attention. I claim for my "ligature tightener," that it is clean, simple, convenient, and efficient; that it will tighten a ligature around a pedicle of any thickness, up to the limit of strength of the ligature; that it does away with traction of the pedicle; that its power can be readily adjusted to given needs; that it can be used as a substitute for the écraseur in certain temporary uses of constriction; and that it also has a distinct use in tightening a suture where, as in a cleft-palate operation, it is desirable to draw on the suture without pulling on the delicate tissue constituting the border of the wound.

A smaller instrument would, however, be desirable in such light work.

An excellent opportunity to test the instrument was afforded me in an operation for splenectomy done by Dr. J. A. Wyeth. Double strands of a large-sized silk ligature were tightened in a single tie around a very thick spleen pedicle, the latter being held by a Smith clamp. Sufficient traction with the index fingers pulling on the ligature, at a depth of several inches under the border of the ribs, was not possible. Applying my instrument, the tissues of the spleen were saved from laceration, and the ligature tied tight without any difficulty or loss of time.

The method of using the "ligature tightener," is to first pass the ligature around the pedicle, and make a single tie. Then holding the instrument in the right hand, and the two ends of the ligature in the left hand, pass the ends of the instrument under the strands held by the left hand, and between them to the knot, wrapping the ligature around the cleat at the joint of the instrument, to hold the ligature taut, then compressing the handles, the ligature at the pedicle is constricted to the degree required.

The instrument is eleven and a half inches in length.

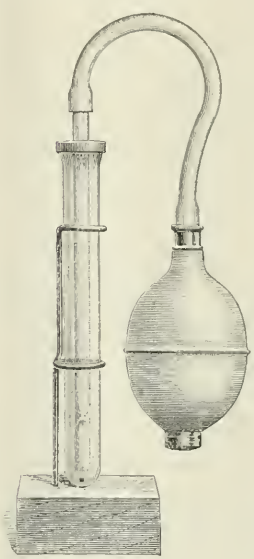
It is manufactured by Messrs. Lincoln & Lachesi, No. 149 East Twenty-third Street.

A NEW CARBONOMETER.

By W. MOLESWORTH, M.D.,

BROOKLYN, N. Y.

I WISH to invite the attention of the profession briefly to my new Carbonometer, believing it to be the only convenient, cheap, and portable device of easy application, for determining the excess of carbonic acid in the atmosphere, in school rooms, sick-rooms, hospitals, mines, tenement-houses, etc., where absolute accuracy is not required. While the thermometer shows the temperature of a room, the barometer the density of the air, and the hygrometer its moisture, we have had no simple device for testing its pollution as the result of combustion or respiration. When the actual health of the occupants of any given apartment is taken into consideration, there is no one thing of more importance than the quality of the air itself; and, recognizing the fact that there is no better test of its pollution than the per cent. of carbonic acid which it contains, by aid of the Carbonometer you can approximate the quantity near enough for ordinary use, and it should be found in every school-room or other apartment subject to vitiation of its air.



Each apparatus consists of a glass test-tube about five and a half inches long and nine-sixteenths of an inch in diameter, together with a smaller tube about six inches long, contracted about one inch from either end, with a valvular rubber bulb and tube to attach; also a rubber ring to fix its depth in the test-tube, a wooden and wire stand for supporting it, with a small bottle each of lime-water and vinegar, and a little brush for cleansing the test-tube.

Fill the test-tube for about one inch, up to the horizontal line, with a perfectly clear saturated solution of lime-water; take the smaller tube with bulb attached,

adjust the rubber ring so that it will hold the tube about three-eighths of an inch from the bottom of the test-tube; gently compress the rubber bulb till all the air is expelled and then allow it to fill again with moderate rapidity, and so continue as often as desired. If, after filling and discharging the bulb six or eight times, the opacity of the lime-water obscures the black spot on the base of the stand the air is absolutely unfit to inhale; and if, after filling the bulb fifteen to twenty times, the black spot is obscured, the observer looking downward from the top of the test-tube through the lime-water, the air is unfit for continuous respiration. In good air the spot ought not to be obscured in thirty or forty fillings of the bulb, and in pure air not at all. This instrument should be used in daylight, and the test-tube washed out with the brush or otherwise after each observation; if incrustations of carbonate of lime form on the tube, remove with a little vinegar, after which wash thoroughly with pure water and wipe dry.

To obtain an idea of its workings, fill and discharge the bulb eight or ten times with the exhalation from your own lungs, and observe its action on the lime-water.

A NEW PHARYNGEAL CURETTE.

By EMIL MAYER, M.D.,

NEW YORK,

SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

From designs presented, Messrs. Tiemann & Co. have made for me a pharyngeal curette, for scraping the posterior pharyngeal wall, and the removal of such portions of adenoid tissue as lie low down in the pharyngeal vault.

The illustration shows the instrument about half size. The cutting surface is on the horizontal bar only. Owing to its shape, any portion of the pharynx can be reached, and the instrument, being all of one piece, can readily be rendered aseptic.

238 East 116th Street.

Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

The Late Professor Charcot.—No one who has attended the clinics of this celebrated professor, or met him socially, or consulted him, but will read of his death with regret. Although an indefatigable worker, and always occupied, yet he never refused an audience to any who sought his counsel, and his uniformly courteous and kindly bearing endeared him to the poor as well as the rich. He was particularly fond of Americans, and singled them out for his favors. I have known of his intervening with the Paris Faculté in their behalf on more than one occasion. His clinic at La Salpêtrière Hospital was one of the most celebrated in Europe, and the hospital one of the largest, the buildings occupying about seventy-seven acres, and, including the *personnel*, can accommodate five thousand people. It became a hospital in 1657. Dr. Charcot entered the institution as *interne* in 1852, became physician in 1862, and was appointed Professor of Diseases of the Nervous System in 1881, the chair being created by the faculty especially for him. The afflux of patients from all countries furnish a vast amount of clinical material in every department of neuropathology, and the numerous and well-mounted laboratories at this hospital, and its original and complete method of study and teaching organized by Professor Charcot, and the corps of distinguished pupils and assistants that surrounded him, go to make up an institution of the utmost importance to the medical world. Dr. Charcot impressed his personality upon all who came in contact with him. He had a grave, kindly face, resembling in profile that of Dante; his manner was calm and deliberate, and his lectures were marked by original conception, clearness of diction, and forceful and picturesque illustrations. In his teaching he aimed to unite all the researches that could make it original, sound, and impressive to his auditors, and at the same time productive of substantial results. The labors of Professor Charcot have tended, perhaps, more than any other teacher in Europe, to the propagation of medical knowledge, and the improved treatment of nervous diseases. Even a brief review of his contributions to medical literature, and the changes he has wrought in professional practice, would require a small-sized volume. His published works are recognized text-books in this department of medicine. He possessed a powerful and versatile intellect, and was recognized as an authority in other departments of science than medicine. A few years since, he read a paper before the Academy of Sciences, of which he was a member, on the "Fixed Stars," and it was awarded the yearly prize as the ablest paper of the year. Like all men who have outstripped their fellows, he had his enemies and detractors; but he was ever ready to lend his influence and aid to the young men who came up about him, and among these many who fairly idolized him will his memory be lasting and stir grief sincere.—Dr. Sherwood Dunn, Paris.

The Doctor's Horse.—At the recent annual meeting of the West Somerset Branch of the British Medical Association, Mr. R. J. Collyns made what Americans call a "new departure" in selecting as the subject of his presidential address that useful and long suffering *servus servorum Dei*, the doctor's horse. He discussed the animal's housing, bedding, food, work, and repose, with a thoroughly practical knowledge of his needs and a tender concern for his well-being and comfort, which Ouida and other "zoöphilists" would do well to note. Mr. Collyns pleaded for the efficient ventilation and drainage of stables, and he pointed out that horses are much more likely to take harm from exposure after leaving a hot stable than a cool one. He considers peat-moss litter more economical than straw, but it has the disadvantage of softening the feet of some horses so much that they are more liable to be damaged by the roads. With regard to feeding, Mr. Collyns said the art of keeping a horse in condition is to maintain a just balance between food and work; and as horses, like their masters, differ in appetite and capacity for work, the owner must make it his business, as it is his interest, to become acquainted with their peculiarities of constitution. He strongly recommended maize, given in the proportion of one part to two or three of oats by weight; horses fed in this way are, he said, kept in harder condition and at less cost than when fed on grain consisting of oats alone. He further advised that some hay or chaff should be given with each feed of corn, as this makes the animal masticate the latter more thoroughly. He also insisted on the

advantage of portioning out the food by weight rather than by measure. Mr. Collyns had also much to say about shoeing: his remarks on this subject were interesting, and his criticisms showed clearly that in order to shoe a horse properly a man should have some elementary idea of the structure of the animal's hoof. Had smiths any tincture of anatomy they would not pare away the "bars," the two firm ridges which act as buttresses to prevent the "wall" of the hoof from being driven inward by the superincumbent weight, as many of them are doing now. Are there no courses of technical education for smiths? Goodsir, predecessor of the present distinguished incumbent of the chair of anatomy at Edinburgh, once said, "I love the horse; I have dissected him three times." We do not know whether Mr. Collyns has shown his love in the same way, but he has evidently made careful study of the animal, his structure, his ways, and his wants, which has borne fruit in his excellent presidential address.—*British Medical Journal.*

Statistics of 5,866 Cases of Vaccination.—Mr. Francis Cadell reports, in the *Edinburgh Medical Journal*, for August, 1893, the statistics of the cases occurring during a period extending from July, 1886, to the end of 1891, in the New Town Dispensary, Edinburgh. *Insusceptibility.*—No case has occurred in which an infant has been found insusceptible to vaccination by the arm-to-arm method. *Repetitions.*—61 cases required the vaccination to be repeated owing to want of success on the first occasion. Failure after vaccination with lymph preserved in tubes was found to be greatly more frequent than in vaccination with fresh lymph from the arm. After vaccination with preserved lymph, failure occurred on the first occasion 26 times out of 310 vaccinations, giving a percentage of 8.46. After the use of fresh lymph, failure on the first occasion only occurred 35 times out of a total of 5,556, which gives an average of 6.30 per 1,000. These facts show the importance of maintaining the efficiency of the large vaccination stations, where fresh lymph can be constantly used for vaccinating. *Erysipelas.*—Seven cases of this dangerous accident occurred, and in almost every case the dwelling-house of the family was found to be damp or otherwise unhealthy. *Suppuration of Lymphatic Glands.*—This complication of vaccination also occurred seven times out of 5,866 cases. *Syphilis.*—There has been no case of syphilitic infection. An additional protection against the propagation of syphilis by vaccination would be to make the age-limit the same for Scotland as in England, where infants must be vaccinated before they are three months old. An infant which showed marked syphilitic symptoms at three months old might appear healthy before reaching the sixth month. In this way the risk of using tainted lymph is greater here than across the Border. *Deaths.*—Two deaths resulted from the complications of vaccination—one from erysipelas, the other from blood poisoning following the suppuration of a lymphatic gland in the axilla. Both deaths took place about three weeks after the operation. *Revaccinations.*—Only 45 revaccinations were performed. The large proportion of these were on boys between the ages of twelve and fourteen, employed at the General Post-Office. Among the laboring classes few come to the dispensary to be revaccinated, and these only do so when compelled by the rules of their employers. It would be much to the advantage of the community were revaccination made compulsory.

Dying Declarations. — Physicians are frequently charged with dying declarations. The law governing their admissibility in evidence is well settled, says the Supreme Court of Alabama, in the case of Blackburn *vs.* State, just reported (13 Southern Reporter, 274). Such declarations are not admissible unless they appear to have been made under a sense of certain and impending death. It is not what the court which passes upon their admissibility may believe the condition of the deceased was, for, although it may appear to the court, or to anyone capable of thinking rationally, that there was no possible hope of recovery, yet the question aside from that is, What was the state of the declarant's mind when the declarations were made? Did he appreciate the fatal character of his injury, and were his declarations uttered under the sense and solemnities of impending dissolution? If so, then, "when the death of the deceased is the subject of the charge, and the circumstances the subject of the dying declarations," they may be admitted in evidence; otherwise not.—*Medical News.*

The Diagnosis of Typhoid Fever.—Dr. V. Filípovich, of Odessa, has remarked that, in all the cases of typhoid fever that have come under his notice during the last two extensive epidemics in Odessa, there have been a peculiar induration and yellowish or orange tint in the prominent portions of the plantar and palmar surfaces, instead of the reddish color to be observed in healthy subjects, or the bluish tinge which those parts assume in a cyanotic patient. This yellowish appearance is to be accounted for by the enfeebled action of the heart, the incomplete filling of the capillaries, and the dryness of the skin in typhoid fever. The sign is so constant and so well marked, that Dr. Filipovich thinks that it should be looked upon as affording important assistance in the diagnosis of doubtful cases. That it is in no sense peculiar to the two epidemics that occurred in Odessa is shown by the observations of Dr. Skibnevski, who states that he invariably observed it during an epidemic in the neighborhood of Moscow.—*Lancet.*

THE TREATMENT OF EXOPHTHALMIC GOITRE, BASED ON FORTY-FIVE CONSECUTIVE CASES.[1]

BY A. D. ROCKWELL, A.M., M.D.,

NEW YORK.

IN considering this strange and intractable disease I shall enter into no speculations as to its pathology, for the reason that all explanations of the phenomena that attend it are in the main conjectural. Neither shall I take time in discussing its etiology or its well-known symptoms, for these can be found in every text-book on Neurology, with little variation of detail. The evidences of pathological anatomy have thus far been so thoroughly negative that we are left to the symptoms alone for guidance in treatment.

These are, however, so positive and suggestive as to afford ground for a rational therapeutics, the end of which must be to regulate and give tone to nerve force, and to equalize the circulation.

In an experience including the treatment of forty-five cases of exophthalmic goitre, dating from 1876 to the present time, a period of sixteen years, I have been enabled to clinically study the disease very thoroughly, and form an opinion as to the benefits to be derived from certain methods of treatment not altogether in accord with prevailing opinions. In short, I hold that the prognosis in this disease is better than is generally believed, and if my results have been more satisfactory than others that have been reported, it has been due to a more rational use of the remedy which has been my main reliance, and greater thoroughness and persistency in its application.

The remedy to which I refer is electricity, and while I by no means exclude the administration of drugs in the management of this disease, they are in my hands regarded as supplementary to the chief remedy, and subject to changes according to the indications in each individual case. The surprising lack of unanimity of opinion in regard to the efficiency of medicinal treatment is due to the fact that, not only have those drugs that have proved beneficial in some cases failed to do good in others, but sometimes a drug that has in one case proved palliative has in another seemed to do harm. Iron, for example, is a universal remedy that is perhaps in the majority of cases fully indicated and is well borne, but I have occasionally found it to be productive of unpleasant symptoms even when anæmia existed, and have been compelled to discontinue its use. The statement of Von Graefe, that iron is useless in the height of the malady, but that it does good when a certain amount of improvement has occurred, is an observation of value, and founded upon an extensive experience.

My own experience has not been very favorable to the use of quinine, strychnia, or arsenic, and I now rarely administer them, and I believe the iodides often do more harm than good.

Belladona has been highly recommended, and is undoubtedly of value. Carbazotate of ammonia I have used in but one case, but discontinued it after ten days, on account of the gastric disturbance that it seemed to occasion. Digitalis is by some believed to be useless in this disease, on the theoretical ground that it directly stimulates the muscular fibres of the cardiac vascular system. While the value of this remedy is now well recognized, there still exists much difference of opinion as to the method of its action. It has been regarded as a tonic, a stimulant, and as a sedative. The latter view, as is well known, was taught by Trousseau long ago, who held that it occasioned contraction of the superficial blood-vessels, thus producing diuresis, very much on the same principle as the action of fright or cold. In a recent discussion[1] Professor Crocq held that digitalis was not a sedative nor a cardiac tonic any more than alcohol is a tonic to the brain. It is simply a stimulant. Another view is that digitalis acts on the pneumo gastric and sympathetic nervous system, thus regulating the action of the heart. By one the remedy is believed to act only on the left heart, by another on the right heart as well, retarding the action of both. But whatever theory is accepted, obstinate experience will not wheel into line at the command of any theory, however plausible.

On the theory of the stimulant and tonic action of digitalis I hesitated for a long time to use it in this disease, but when I finally came to put it to the test of actual trial I was most agreeably disappointed in the results, especially when combined with certain other remedies to which allusion is made further on.

If the heart seems abnormally strong in exophthalmic goitre, this is not by any means always the case. Very frequently there is enfeeblement of the myocardium, and digitalis is in many cases useful in slowing the rapid systole associated with it. The condition of the heart thus becomes improved by the physiological rest it obtains through prolongation of the diastole.

Yet, like iron, digitalis may under certain conditions prove not only useless but harmful; but like iron, and especially in combination with iron, it possesses undoubted value. In what may be termed sthenic cases, where the excitability of the heart is great without enfeeblement, digitalis is certainly contra-indicated, and one such case will be found in this report. In this case good results were obtained by substituting veratrum viride for digitalis.

Strophanthus has received high commendation, and on theoretical grounds it is recommended in preference to digitalis. While both tend to lengthen the interval between the contractions of the heart, strophanthus is supposed to contract the calibre of the arterioles in less degree than digitalis, and is to be preferred as not increasing the work of the heart to the same degree as the latter.

In conjunction with digitalis or strophanthus, and iron, ergot and bromide of zinc seem to me to be distinctly valuable, and I have no hesitation in saying that a combination of these remedies will more nearly fulfil the indications in the majority of cases of exophthalmic goitre than any other single remedy or combination of remedies. There are probably to be found few, if any, who will not accord to electricity an important place among the remedies indicated in exophthalmic goitre, and unlike some others mentioned, it cannot, if judiciously used, do harm even in those cases where it does no good.

Gowers, who does not in general accord to electricity a very high place in therapeutics, yet says that in this disease it is followed in many cases by a distinct fall in the frequency of the pulse (amounting to 10 and even 20 beats per minute), and sometimes by a slight diminution

[1] Read before the Pan-American Medical Congress, Therapeutic Section, September 7, 1893.

[1] Academy of Medicine, Belgium, January 28, 1893.

in the size of the thyroid. In one case he observed the pulse fall from 90 to 72, a lower rate than had been counted during the preceding two years.[1] He adds, however, that such effects are usually transient, although repeated applications certainly sometimes cause a slight degree of permanent improvement. He has not seen more than this.

Even such results as Gowers describes are not to be despised, but the difficulty with his efforts, and with others who have written upon this subject, is the utter inadequacy of the strength of current used, and, above all, so far as my observation goes, in the incomplete and haphazard way in which the applications are administered. Gowers would use a weak galvanic current, sufficient to cause merely a slight tingling of the skin, while others who have written extensively upon the subject are content with two or three milliampères. These authorities do not seem to appreciate the fact that in the therapeutic use of electricity they are dealing with a hide-bound body which offers such a resistance to the passage of the current that our ingenuity is taxed to its utmost in order to overcome this resistance and get into the body a sufficient quantity of electricity to appreciably affect the cerebro-spinal system and the nervous system of vegetative life, the pneumo-gastric, the great sympathetic, including the vaso-motor system of nerves. These large current strengths cannot, of course, be used with small electrodes applied in the ordinary way over the region of the sympathetic and vagus in front of the neck, and from the mastoid process along the inner border of the sterno-cleido-mastoid muscle to the manubrium sterni. Here, although the current strength should be much higher than is usually recommended, it is rarely possible to exceed ten or fifteen milliampères. For the greater strength of current, large electrodes, preferably of sculptor's clay, should be applied both to the back of the neck (cilio-spinal centre) and solar plexus. With electrodes in this position I have frequently used as high as sixty milliampères, and with results the most beneficial.

I do not, however, recommend such apparently heroic treatment. Idiosyncrasies vary, and there is probably no remedy to the effects of which there is a more varying degree of susceptibility than to electricity. Every case is a law unto itself, and should be studied independently, with the exercise of judgment and common-sense in its management.

But if my results in the treatment of this disease have been exceptionally good, I attribute it in part to the fact that I have not confined my efforts to the use of drugs and the galvanic current alone, but have in many instances combined with these methods the most thorough and persistent treatment by the method of general faradization. While the methods of Eulenberg and Gutman in using simple localized faradization in the vain attempt to affect directly the sympathetic, and the faradization of the precordial region by Vigoroux and Charcot, may possibly do some good, they cannot compare in efficiency with general faradization, a method which has been abundantly tested and which rests upon a sound physiological basis. What localized faradization is to an individual part or organ, general faradization is to the whole body. In exclusively localized faradization the increase in the processes of waste and repair and improvement in nutrition are mainly confined to the part which is traversed by the current, but in general applications these effects are appreciated by every part of the system. The improvement which each part or organ receives from the treatment reacts upon every other part, and every effect becomes in its turn a cause. While, therefore, I consider electricity of rather more importance than any other remedy in the treatment of this disease, yet in many cases the most rigid and conscientious observance of certain fixed rules in regard to eating and drinking, and the avoidance not only of excess in every department of mental and physical hygiene, and even the repression of ordinary and legitimate emotion and passions, become very essential. For the majority of these forty-five cases of exophthalmic goitre I am indebted to the kindness of the various members of the profession, most of whom have watched with interest the progress of the cases and have noted both the successes and failures.

I do not propose, however, to relate the failures nor to report in detail the cases (only too many in number) which experienced only partial and incomplete relief. Some absolute failures occurred, but not many. It is rare, indeed, that through the combined method of hygiene, diet, drugs, and electricity, the disease fails to be in some degree favorably influenced, for out of these forty-five cases there were but three that received no benefit whatever, and these were not even temporarily relieved.

Twenty-seven of these cases were benefited, some of them in very great degree, others only slightly. Some of those that were much benefited relapsed and received further treatment with good results, while others have been lost sight of and their subsequent history is unknown. In fairness, however, it must be said, that while the most persistent treatment failed to do more than slightly improve many of these cases, some of them, which otherwise possibly might have been benefited, discontinued treatment after a comparatively short period.

Fourteen of these cases either fully or approximately recovered, and as the first six have been reported,[1] I shall very briefly allude to them, giving in full only the eight more recent cases.

Case I.—Mrs. G——, aged about forty years, was referred to me May 3, 1876, by Dr. S. S. Purple, and during the treatment, and for many years after, until her death, was under the constant observation of Dr. J. J. Griffeths, of New York. Pulse was violent, and from 115 to 140; exophthalmus prominent, and thyroid considerably enlarged. First symptoms, three years previously. Approximate recovery, the only symptoms remaining after several months of treatment being slight exophthalmus and thyroid swelling with occasional cardiac palpitations.

Case II.—Mrs. H——, aged forty-two, came March, 1877. Pulse, 85 to 90; goitre quite large, but no exophthalmus; recovery.

Case III.—Mrs. E——, aged thirty-one, sent by Dr. I. B. Read, of New York, October, 1878. The three cardinal symptoms present. Pulse, 120 to 125, and occasionally 150; recovery.

Case IV.—John L——, aged twenty-nine, came July 6, 1879. The three cardinal symptoms present in marked degree. Pulse, 125; recovery.

Case V.—Mrs. C. H——, came September, 1879. with the three cardinal symptoms well marked. Pulse, 110; recovery.

This case examined on one occasion by Dr. P. B. Porter.

Case VI.—Miss M——, aged twenty-two. Referred to me by the late Dr. C. B. Belden and by Dr. J. E. Stillwell, of New York, October 18, 1879. All three symptoms present, the exophthalmus and thyroid enlargement in greater degree than the excitation of the heart, which beats only at the rate of 88 per minute; recovery.

Case VII.—Miss B——, aged about twenty, was referred to me June 11, 1882, by her physician, Dr. A. R. Carman, and by Dr. Richard Van Santvoord, of New York. This case was a very aggravated form of Graves's disease.

The eyes were unusually prominent, the goitre large, and the pulse seldom if ever under 140, and frequently reaching 160. The beginning of her symptoms dated back between two and three years, and had gradually reduced her until she was unfitted for all active effort. The patient received some seventy applications, resulting in a permanent recovery. Her present condition, ten years since the cessation of treatment, is this: Pulse, 75 to 85, with hardly a perceptible enlargement of the thyroid or protrusion of the eyes. The patient's general health is.

[1] Disease of the Nervous System, p. 1214.

[1] New York Medical Record, vol. xviii., No. 11.

and has been, excellent for years, and she can engage without restraint in all the ordinary pleasures and activities of life.

Case VIII.—Miss D——, aged twenty-nine, was referred to me by Dr. Stephen Wickes, of Orange, N. J., March, 1885, with the three cardinal symptoms of the disease well developed, the exophthalmus, however, being much less marked than the other two.

The pulse when ordinarily tranquil was 125, sometimes considerably higher, and on one occasion under excitement it beat at the alarming rate of 175 per minute. The heart was slightly enlarged, and the systolic murmur, which is so frequently present in these cases, was unusually loud and could be distinctly heard, even when the ear did not touch the chest.

The disease was not of recent origin, for some four years before, when nursing a sick relative and subject to much physical and mental strain, she first observed symptoms of disturbed heart action, and shortly after the throat and eyes both became affected.

The patient was under observation and treatment until April, 1886, a little more than a year, and in that time received eighty-five applications of electricity, with the result of a gradual but steady improvement not only in the condition of her general nervous system, but in the special symptoms characteristic of the disease. The systolic murmur entirely disappeared, the pulse sank to a permanent rate of about 80, and the eyes resumed their natural appearance. Her general health is excellent.

Case IX.—Miss R——, aged twenty, was brought to me on November 16, 1887, by Dr. F. Myers, of Fort Worth, Tex.

The thyroid was only slightly enlarged, but the eyes protruded to a degree that greatly altered her expression, and was the source of much annoyance. The heart pulsated at the rate of 120 per minute, but on occasions of excitement and physical fatigue I have counted it as high as 150. These symptoms had existed some three years, but all her bodily functions were normal, and, contrary to what is usually observed, her general health and strength first-class. This was one of the few cases that have come under my observation when digitalis seemed to do harm.

Whenever it was given in any considerable dose, either alone or in combination, the excitability of the heart was undoubtedly increased, and this effect I attributed to the fact that, associated with the over-excited cardiac contractility there was absolutely no enfeeblement of the heart muscles. Strophanthus proved equally unpleasant in its effects, while veratrum viride was found to exercise the most salutary influence. No other drug was given for its direct effect upon the heart, and the treatment was practically confined to electricity alone and extended over a period of fourteen months. From November 16, 1887, to March 23, 1888, she received sixty-six applications, with an interval of rest until October 17, 1888, when she received forty-seven additional treatments between that date and January, 1889. During the first two months of treatment there were but slight evidences of improvement, but during the following two months the eyes became less prominent and the goitre perceptibly decreased in size. In March, when she temporarily discontinued treatment, the pulse had not only fallen to 100 beats per minute, but was not readily susceptible to ordinary emotional or physical causes. Seven months after, when she returned, I found her in about the same condition as when she left. Resuming treatment on October 17th, she perceptibly gained during the next three months, and was finally discharged as approximately cured, the pulse seldom rising above ninety, with but slight evidences of exophthalmus or thyroid enlargement. The patient has since married.

Case X.—Mr. B——, aged about thirty-five, was referred to me by Dr. E. Hochheimer, of New York, January 5, 1888, with comparatively slight but persistent evidences of the disease. The pulse was 100, with slight swelling of the thyroid. There existed neurasthenia with extreme melancholy, and while there was hardly any exophthalmus, there was present the somewhat rare symptom of obstinate œdema of the eyelids. The patient fully recovered after forty applications of electricity, extending over a period of three months.

Case XI.—Mrs. M——, a widow aged thirty-one, consulted me January 9, 1888, with the following history: Five years before, her first child was born after a prolonged and unusually severe labor. She convalesced slowly, and in a few months more or less began to notice an undue activity of the heart, with shortness of breath, whenever she ascended the stairs or walked more rapidly than usual. These symptoms did not greatly increase until about two years ago, when the heart began to give her more trouble, and she first noticed a "a strange appearance about the eyes and a fulness in the neck." The eyes were now very prominent, the thyroid about as large as a small hen's egg, and the pulse-beat from 128 to 135 per minute. She was markedly anæmic and extremely nervous. The patient was under treatment from January 9th to April 7th, and then again from June 8th to July 29th, receiving in all some fifty-five applications of electricity.

Recovery has been approximate and permanent. The eyes are perhaps slightly more prominent than natural, but not to a degree to excite comment. There are only traces of the enlarged thyroid, while the heart pulsates at a uniform frequency of between 80 and 90 per minute. Her general nervous condition also improved to such a degree that she now counts herself a well woman.

Case XII.—Mrs. E——, aged thirty-four, was seen with Dr. J. H. Gunning, of New York, April 21, 1888. Four years before, she had miscarried, and subsequently had worried much over domestic troubles. Three years before, her heart began to trouble her, and soon after she observed a slight protrusion of the eyes and some enlargement of the thyroid. When Dr. Gunning and I first saw her the eyes were prominent, but the gland was only slightly though perceptibly enlarged. The pulse ranged in frequency from 115 to 135, and on one occasion we counted it at 165. The patient has lost much flesh, menstruation was irregular and profuse, and with a generally nervous condition was associated a very decided muscular tremor whenever she attempted to move the hands, simulating in marked degree the tremor of paralysis agitans. The patient was under treatment, with some intervals of rest, for seven months. During this time she received seventy-three applications of electricity and was discharged approximately cured. The pulse never rose above 100 and was usually at 85, the tremor had entirely disappeared, and the eyes were quite normal.

Case XIII.—Miss S——, aged twenty-five, came to me August 6, 1890, through the kindness of Dr. W. T. Giddings, of Gardiner, Me., with well developed evidences of Graves's disease. The eyes were slightly though distinctly protuberent. The thyroid gland was enlarged to the size of a very large almond, while the pulse beat at the uniform rate of 120, running up, however, on slight exertion, much higher. All exercise was exhausting, and ascending the stairs especially so. That the disease was not of recent origin was evidenced by the history given. As far back as 1885, while a pupil at Wellesley College, the act of recitation would cause her hands to tremble and perspire, her heart to beat tumultuously. When the cause of excitement was over, the heart would resume its normal action; but she noted, as time went on, that this instability of the heart-beat became more frequent and prolonged, until finally it "went wrong" always, as she expressed it. It should be stated that the patient was somewhat anæmic, and since the age of fourteen has suffered from myopia and astigmatism. In 1887, and then again in 1889, she had slight attacks of the grippe, which occasioned a decided increase in the severity of her symptoms. The symptoms, however, that were most distressing, if not the most serious, were the frequent and terrific headaches from which she suffered.

These were associated with intense nausea, lasting some twenty-four hours and recurring almost every week. The

patient was first treated through a period of seven months to March 19th receiving some thirty-seven applications of electricity, improving gradually in every symptom.

In July treatment was again resumed and continued until she had received some twenty-five additional applications. To this date the patient, who is under constant observation, retains all the benefit that she at first received. The pulse is 70 to 80, the eyes normal, and the thyroid enlargement gone. More perhaps than all else, she has been so relieved of the distressing headaches and nausea that it is only at long intervals that they occur, and with no great severity.

Case XIV.—Mrs. J., aged thirty-four, was referred to me by Dr. George W. Harrison, of New York. She was in an extremely nervous condition, with a very decided enlargement of the thyroid, a pulse of 130, but no exophthalmus. She first observed some disturbance of the heart-action three years before, and a few months thereafter she detected evidences of a swelling in the throat. This patient was treated every day for two weeks, when she was obliged to leave town, but in that brief period, contrary to my expectation, all the symptoms were very decidedly alleviated. After a thorough and prolonged séance of galvanization of the sympathetic, central galvanization and general faradization, the pulse invariably subsided some fifteen or twenty beats, only to rise somewhat during the next few hours. It was every day noticeable, however, that the pulse beat with less violence and frequency, and when she left town it rarely rose above one hundred.

The method of treatment adopted by me was carried out by her family physician, Dr. J. W. McLaughton, of Austin, Tex., and according to a communication from the patient, the pulse finally reduced to 80 and 85.

THE USE OF ACONITE IN THE TREATMENT OF TETANUS.

By L. L. von WEDEKIND, M.D.,

UNITED STATES NAVY.

Having recently successfully treated a serious case of tetanus, using in conjunction with other drugs large doses of the tincture of aconite, and believing, from close observation of the case and the behavior of the drug, that the patient's recovery was due in large part to its beneficial action, I give for these reasons a summary of my notes of this case.

The exciting cause of the trouble I believe to have been the tropical influence of eight degrees north, assisted by an ulcerated tooth; without this tropical influence I imagine nothing peculiar would have occurred.

We lay in the harbor of Corinto, Nicaragua, for nine days, sailing thence south. On June 11th, at sea, one day out from Corinto, the patient, a hale and hearty man of about thirty years, reported at morning sick call, complaining of inability to move the jaws. He had for three days been suffering with a toothache, though an examination of the affected part shows no swelling. The jaws firmly locked and the muscles of the face, neck, and back rigid. Much pain in the back and neck. Face anxious and eyes wide open and staring. Pulse, 110; temperature, 102.4° F. Owing to the locked jaws and tightly drawn lips, speech is very indistinct. Patient put to bed, and at 9, 11 A.M., 1, 3, 5, and 7 P.M., or every two hours during the day, the following mixture was given: Tr. opii, ℥ xv.; chloral hydrate, gr. xx.; potass. bromid., gr l. This was mixed with water and administered through the spout of a feed-cup, while patient was in a reclining position. Whiskey and beef tea given whenever patient was thirsty.

At 4 P.M. of the first day, no effect of the medicine was noticed, not a wink of sleep, and pain still well marked. The temperature at 3 P.M. had reached 103.8° F., when ℥ v. of tinct. aconite was given and repeated at 4 and 5 P.M. At about 5 P.M. the patient dropped off asleep and slept until 7 P.M. After the administration of the aconite, a change was noticed: pain less, and a gentle moisture in general over the whole body, also a marked feeling of relief.

The opium and chloral were now at work, and the rest and sleep gained from their action retarded the rapidly reducing strength.

At 7 P.M. the temperature was 102.6° F., and the patient was given a bath of equal parts of cold water and alcohol. Every four hours during the night the opium mixture was given, and the aconite every three hours. The action of this drug was noticed early, and though the dryness of the throat was exceedingly distressing, the general relief was so marked that the dose was only reduced when the effect upon the general system was undoubted.

At 9 A.M. of the second day the temperature had reached 104.2° F., with a pulse or 120. The aconite administered in about eighteen hours amounted to about three-quarters of a drachm, still its controlling influence upon the temperature seems to have been slight. However, without it, the temperature might have gone much higher.

The opium mixture was given as on the first day. The pain in the neck and back, though less, is still very severe and sleep is almost impossible. Bath of cold water and alcohol frequently given; thirst very great and the mouth and throat dry. At 3 P.M. the temperature, despite both external and internal treatment, reached 104.8° F. Tr. aconite ℥ v. every hour for three doses now given, this in addition to that regularly given during the day and night.

At 7 P.M. of the second day the effect of the drug was such as to almost prostrate absolutely the patient, *still*, relief after the administration of the hourly doses was, as he expressed it, "heaven to him." Sensation almost gone, tingling marked, and the temperature 1° less. The asthenia, owing to the drug more than to the disease, though very marked, is not alarming. Opium mixture every three hours from 6 P.M. At midnight the pain of the muscles of the neck and back was such as to render sleep impossible. No aconite had been given since 6 P.M., and the effect of that previously administered had worn off. Patient was now given of chloral, 25 grains; bromide, 50 grains, tr. opii, ℥ xxx., and 5 drops of aconite. At 3 and 7 A.M. the opium mixture of the first day was repeated.

Third day.—Passed a restless night; treatment same as on first day. At 4 P.M., temperature 103.6° F., and pulse, 130. No change in the rigidity of jaws, pain slightly less, though the agony in back and neck exceedingly marked and very prostrating. The opium mixture given every four hours, aconite ℥ v. every three hours, and its action very closely watched. Stimulation as necessary.

Fourth and fifth day as above in general progress and treatment. On the evening of the fifth day, the jaw very minutely relaxed; the flat handle of a silver fork can enter between the teeth. Temperature, 101° F.; patient sleeping better.

On the sixth day the opium mixture every five hours, and aconite every four.

On the seventh day, temperature, 100° F.; jaws somewhat relaxed and movable through about half an inch. The muscles of the back and neck exquisitely tender.

On the tenth day the jaws wholly relaxed and all medication ceased.

From the facts obtainable in reviewing the above case, the conclusions I reach are: That the temperature was controlled to some extent—very probably to a great one—by the aconite; this balancing, the saving of strength thus obtained, as opposed to the loss occasioned by the drug. If of reflex action in incipiency, and continuous throughout the whole course, this disease should in great measure be controlled by aconite, judging by its known physiological action. I am almost positive of its ability, in this disease, to assist the action and consequent relief and benefit obtained by the exhibition of opium, chloral

and bromide. Its depressing action is easily overcome, and the assistance it offers in maintaining strength by inducing the action of associates, easing pain, and causing sleep, counterbalance the danger of its administration in large, frequent, and often dangerous doses.

U. S. S. Alliance, August 16, 1893.

THE PREVENTION OF TRUE AND FALSE DIPHTHERIA.

By F. W. KOEHLER, M.D.,
LOUISVILLE, KY.

Few diseases have been the subject of more constant study, and few have finally been more thoroughly elucidated, than diphtheria. In the light of bacteriological research, what is this dreaded disease? The word signifies a false membrane (literally a skin), hence every membranous inflammation might be called diphtheria. There is one form, however, that produced by the Loeffler bacillus, which is particularly dangerous, and rightly or wrongly, the name has been given to it exclusively; the other varieties—due to certain streptococci and staphylococci—being now classed under the comprehensive terms, pseudo or false diphtheria, diphtheroid, etc. There is then, only one true diphtheria, but there are a number of varieties of the false. A very important point is, that the true and false often resemble each other so closely that they cannot be distinguished by the naked-eye appearances alone. Only by means of a bacteriological examination of the membranous exudates can an accurate diagnosis be made; hence every case should be thus examined. Physicians not familiar with the method should either learn it, or send their specimens to some competent bacteriologist for examination. The city of New York has set a grand example in establishing a special laboratory for the free diagnosis of these cases. It is to be hoped every city in the land will soon follow the example. Why is it so important to make an accurate diagnosis in every case? is often asked. Chiefly because it enables us to determine what is really accomplished by any particular method of treatment of diphtheria, and also because it helps us to render an intelligent prognosis. As I believe in isolating cases of false as well as true diphtheria (for reasons to be given presently), I do not share the opinion of some physicians who consider an accurate diagnosis mainly valuable as a means of deciding which cases to isolate and which not. The reports of results obtained by various methods of treating diphtheria, published until very recently, have been next to valueless, because the cases of false diphtheria have not been properly separated from the true. Hereafter, however, everyone recounting his success in the treatment of diphtheria will have to state whether the Loeffler bacillus was present in each case.

Pseudo-diphtheria gets well almost invariably, no matter how we treat it, and it is only for the true form of the disease that an effective specific treatment is wanted. There are reasons to believe that such a method has been discovered by Behring. He claims, most positively, that his immunizing serum will not only prevent the disease, but also invariably cure it, if used promptly enough and in sufficient quantity. As the method is being systematically tried in several hospital wards in Berlin, we shall soon know what value it possesses. It is to be hoped that the time may soon come when we shall be able to prevent diphtheria, by inoculating everyone at stated intervals with a little of Behring's serum or some other substance. This time may, however, be longer coming than we wish, hence it behooves us to consider whether we cannot accomplish more in the prevention of diphtheria with the means at hand, than we do. I am convinced that we can, and the object of this paper is to advise the adoption of certain simple, but, I think, effective measures against this justly dreaded scourge. Who doubts that the number of cases could be reduced to an insignificant few, if we fought diphtheria as we do cholera? And why should it not be fought as vigorously? Considering the terrible character of the disease and the great mortality from it, there is a strange laxness observable in the measures usually adopted against it.

The conviction has gradually forced itself on me that we should adopt as rigid measures against false as against true diphtheria. The various forms of pseudo diphtheria are not very dangerous diseases, but they undoubtedly pave the way for the true. Furthermore, a combination of true with false diphtheria is much more dangerous than the former alone. The septic and pyæmic symptoms so often noted in these mixed cases have been shown to be due to streptococci, and not to the Loeffler bacilli. It is consequently almost as important that a patient with true diphtheria be prevented from taking in addition the false, as that a patient with the latter be prevented from taking the former. Roux and Yersin, those excellent observers to whom we are indebted for so much valuable knowledge of diphtheria, have also shown (*Annales de l'Inst. Pasteur*, No. 7, 1890) that weakened Loeffler bacilli can be made active and virulent again by inoculating streptococci with them. All of these facts demand that false diphtheria be guarded against as rigidly as the true.

At the outset of our inquiry into the preventability of diphtheria, the question presents itself: Can we give to the individual greater resisting power against the disease? Undoubtedly this can be done, both by general and local measures; best by a combination of the two. It is well known, of course, that we are less prone to infectious diseases when in robust health than when weak and sickly. Close inquiry discloses the fact that many children with diphtheria have been ailing in some other way before contracting it. There are a number of agencies that quickly lower the vitality of the bodily cells, and thus render them more vulnerable to the attacks of virulent germs. Chief among such causes are the following: hunger; physical and nervous exhaustion; exposure to cold and wet (or either alone); and mental shock and depression. In a considerable number of my cases of diphtheria the onset of the disease quickly followed some unusual exertion, with incidental exposure to cold and wet, and in one case it occurred during the shock and mental depression produced by harsh punishment, the patient, a very sensitive child, received at school. An interesting observation, indicating how potent a factor exposure to cold is in the production of disease, was reported (*Lyon Méd.*, October 19, 1890) by Lipari. He injected pneumonic sputum into the bronchi of numerous animals, but was never able to produce pneumonia thereby unless he exposed the animal to cold immediately before or after the injection.

It is a well known fact that our upper air passages swarm with numerous varieties of bacteria (and no doubt the Loeffler bacillus is among them quite frequently) at all times, but that they are incapable of much mischief while we are in good health.

Through such depressing agencies as have just been mentioned they are given an opportunity of multiplying and increasing in virulence, and finally inducing disease. Hence the importance of maintaining a high standard of general health. Speaking of the bacteria that constantly infest the cavities of the head and the throat, brings me to a most important subject, viz., the local preventive treatment of diphtheria and pseudo-diphtheria. Results that I have obtained by such treatment have prompted me to write this article. How to destroy the bacteria referred to, or at least to weaken them to such a degree that they shall cease to be a menace to health, is a question that naturally at once suggests itself. In a paper published in this journal a number of years ago, I insisted that the toilet of no child should be considered complete until its mouth, throat, and nasal passages had been as thoroughly cleansed as its face. Weak solutions of creolin were advised for the purpose. Since then I have constantly acted on this idea, and feel certain that I have thereby prevented many cases of infectious throat disease. I have, whenever diphtheria has been prevalent, induced a great many mothers to spray the throats and nasal pas-

sages of their children several times daily, and have yet to see the first child systematically treated in this way develop either false or true diphtheria. Some writers desire us to believe that spraying a membrane is bound to irritate it and lead to disease. I am prepared to deny such statements. They are, in my opinion, founded on theory and not on fact, for in my experience an unhealthy membrane improves and a healthy one simply remains healthy, when subjected to daily spraying with mild, warm solutions. Theoretical objections, and exaggerations of occasional observations, should be ignored. Formerly I frequently saw one child after another of the same household develop diphtheria or pseudo-diphtheria, but now, since I isolate every case (whether false or true), and insist on all the well members of the family as well as the sick using antiseptic sprays and gargles, I never have that experience. Isolation does not alone account for it, for I have noted the same absence of secondary cases in small houses and flats where it was impossible to separate the well from the sick. Failure to cleanse and disinfect the nasal passages and throats of children exposed to diphtheria, seems to me, in the present state of our knowledge, next to criminal. Having discussed the question of personal prophylaxis of diphtheria, it is now in order to inquire into the chief sources of infection and to suggest measures for their suppression.

There is no doubt that many cases of false and true diphtheria are contracted at school, and when we study the habits of school-children this does not appear at all strange. The frequency with which chewing-gum is transferred from one child's mouth to another's is alone sufficient to spread the disease. In addition, however, children constantly borrow each other's pencils, and few of them ever write without first wetting the pencil in the mouth. In cleansing their slates they are equally filthy. They use each other's slates indiscriminately, and in cleansing them often pass a finger from the mouth to the slate a dozen times. The chewing of gum, paper wads, etc., causes great activity of the salivary glands, and much saliva is consequently deposited on the floor. Here it dries and leaves an infectious dust which is kept in motion by the shuffling of many feet. Whether many germs are carried out into the atmosphere during quiet breathing is a question, but there is none that every expulsive cough sends out thousands of them; and all the diseases here referred to, cause, of course, more or less coughing. Coupling these facts with another very important one, viz., that school rooms are very badly ventilated during the cold months, we cannot wonder that so many fatal cases of infectious disease are contracted at school. And yet this need not be. Very simple measures would suffice to make the school-room quite safe. If a daily examination of all pupils were made by competent physicians, and every child at all suspiciously ill sent home immediately, the schools would soon cease to furnish the thousands of cases of diphtheria, scarlet fever, etc., that they now do. One or more physicians should be appointed to each school, and as an examination of the nose and throat requires but little time, their work would not curtail the school hours materially. And to what extent would such a service increase taxation? Not very greatly, surely; insignificantly, in fact, when we consider what would be gained. What good citizen would protest against paying a few cents more in taxes if he, in turn, could feel that his children were safe from contagious disease while at school? Of course, from what has been said it follows, also, that the habits of school children should be corrected, that ventilation should be insisted on, and that school-rooms should be constructed much like operating-rooms, to facilitate their cleansing and disinfection.

Defective sewer-pipes, dampness, and lack of cleanliness, account for most cases of diphtheria occurring in private residences. Dr. Fischer's investigations (see this journal, January 28, 1893) have demonstrated the presence of the Loeffler bacillus, the undoubted germ of true diphtheria, in the gases arising from sinks. Hence the importance of a perfect sewerage system. Every city should have a corps of sanitary inspectors, who should allow only sewerage fixtures of approved pattern to be put into buildings. Dr. Fischer comments on the fact that the sewer-traps themselves may become, if not properly flushed, breeding grounds for bacteria. In this connection I will remark that it has often occurred to me, that the waste-pipe of a washstand or sink may be a source of infection. I refer to that part of the pipe between the external opening and the nearest trap. This section of the sewerage system gets the warmth of the house; has quantities of organic matter poured into it; has water more or less constantly running through it; always contains air, and is consequently a most perfect culture ground for many kinds of bacteria. The traps may therefore be in perfect order, and yet we may not be safe. Some device to shut off also this part of the sewerage system from all communication with the atmosphere of the house, seems to me to be badly needed, and I think an opportunity is here offered some inventor. I have occasionally sought to accomplish the purpose by having cloths saturated with some antiseptic solution placed over the external opening, but owing to the carelessness of servants and others, such a plan is hardly feasible. Only during the panic produced by the occurrence of a succession of cases of diphtheria or typhoid fever, would such a measure ever be properly carried out. What is needed is an automatically acting device which will hermetically seal a waste-pipe at its external opening.

Cases of diphtheria also often arise on premises having no sewer connections—in country homes, for instance. Against such cases it is no doubt difficult to direct specific measures. Knowing, however, that the germs of true and false diphtheria can grow only on organic matter of some kind in the presence of moisture, it is in order to keep the house and premises as dry and clean as possible.

Children should also be cautioned against playing about the refuse heaps of stables.

The drinking-water is another source of danger. In the *Deutsche med. Woch.*, No. 29, 1893, Dr. Landmann reports the finding of a virulent streptococcus (the strep. longus) in the water of a well used by a number of families that had been unusually afflicted by diphtheria, or what had been called diphtheria.

Having considered some of the chief sources of direct contagion and infection, I come now to the question of the transportability of the diphtheria germ. It can, no doubt, be safely stated that the disease is not often carried from one person to another by a third—experience proves this—but no logical individual will deny its possibility. Even physicians, or possibly I should say, particularly physicians, may, if careless, thus spread the disease. It happens quite frequently that a child whose throat is being treated coughs violently, and thus transfers a quantity of infectious matter to the physician's clothing. Having dried there, it is later liberated and propelled into the atmosphere by the crumpling of the clothing occurring with every movement of the arms, and what is to prevent its being inhaled by some other child the physician may possibly have taken on his lap for examination? Well founded and logical indeed are Behring's demands, that physicians practise asepsis and antisepsis as rigidly as the surgeons. It is not at all unlikely that we may sooner or later be forced, by the logic of the situation, to adopt clothing that can be sponged off with an antiseptic solution a dozen times a day, if need be. Such clothing is already worn in some of the special hospitals abroad, and why should hospital patients be guarded against infection more carefully than private ones. There is every reason why the exposed clothing of physicians should be made of some material (mackintosh, for instance) that can easily be rendered aseptic. A rubber skull-cap should also be put on before entering the sick-room, and physicians persisting in wearing long beards should spray them thoroughly with some reliable antiseptic after every visit to a contagious case. Until aseptic dress is adopted, we should at least consider it our duty to disinfect most thoroughly any part of our clothing that

may have suffered contamination; and this should be done before going to see the next patient. Those tiresome and illogical individuals in the profession who so volubly declare that diphtheria is not contagious, and that it is unnecessary to isolate a household in which it exists, will no doubt hoot at these suggestions. Unfortunately, the opinion of these persons, though not in itself interesting or valuable, acquires importance because it is misleading and dangerous to an uninformed public. And this danger will probably continue until the law shall hold physicians responsible for every infraction of the principles of asepsis.

HAVE THE RED BLOOD-CORPUSCLES A NUCLEUS?

By WILLIAM MOSER, M.D.,

Assistant Pathologist to St. Catharine's Hospital, Brooklyn, N. Y.

If we define a nucleus as a "special collection of protoplasm marked off by a definite outline from the rest of the cell, and distinguished from it by resisting the action of acids or alkalies which destroy or render invisible the body of the cell, and by imbibing the stain of carmine, hæmatoxyline," etc. (Gray), we find these requirements filled in the nucleus or nuclei of the white blood-corpuscles. But since we know so little of the chemistry of the nucleus or in fact of protoplasm, I feel justified in asking the question, are these properties essential in constituting a nucleus? In determining the question as to whether or not the red blood-corpuscle has a nucleus, I used methylene blue, which we preferred to carmine, hæmatoxyline, etc., for the following reasons:

The stain (methylene blue) was given internally, according to the suggestion of my friend, Dr. J. Fuhs (physician to St. Catharine's Hospital), in one-grain doses three times a day to different patients. The blood when examined by this process is already stained by nature. In short, the patient does our laboratory work. It is obvious that this method removes many objections to artificial processes. The blood, when examined fresh in these cases, showed plainly the nucleus or nuclei of the white blood-corpuscles stained blue. The polynuclear cells (accepting Ehrlich's classification for all practical purposes). were especially well stained. The protoplasm, in contradistinction to the nuclei, remained unchanged. The blood taken from convalescents from fracture showed that the red blood-corpuscles too showed this distinction. In the centre of the corpuscle was found a collection of protoplasm stained faintly but distinctly from the rest of the cell. It did not imbibe a distinctly bluish tinge in these cases, but more reddish, as is seen in the nuclei of the white blood-corpuscles when the blue is given in only half-grain doses twice daily and examined the following day. In certain conditions of anæmia (complicating tuberculosis) the blood showed the stain more pronounced. In specimens now in my possession it is easy to demonstrate a nucleus. In a case of pernicious anæmia the stain was still more apparent—distinctly blue. Now, it is well known that in pernicious anæmia a nucleus can be demonstrated in the red blood-corpuscles in quite large numbers by artificial staining. In a case of tuberculosis now under observation the nuclei are uniformly stained.

I am inclined to believe that by this process of staining (Fuhs's method) we can distinguish a membrane. That the red blood-corpuscle has a membrane was regarded as probable by Kölliker, Richardson, and other able microscopists; but they could not demonstrate it. I am not yet ready to state positively on this point. I could also see by this method of examination (in one specimen) that the red blood-corpuscles were sending out processes in all directions, as we are all aware is so characteristic of the white blood corpuscle. I regret not to have had an opportunity of trying this method in a case of leucocythæmia. I have had an opportunity of examining quite a few specimens of leukæmic blood in Ehrlich's laboratory, and think we are justified in making a diagnosis of this condition from a given specimen according to his teaching. In pernicious anæmia, on the other hand, I am a little at variance with the teaching of Ehrlich in Germany, or Hayem and others in France. I do not believe it has much practical value. It does not give us a clew to the underlying morbid condition. I am also at variance with the teaching of Metschnikoff. While I hope enthusiasts will not use their patients as a substitute for the laboratory, I do hope to see these experiments continued, as they may yet lead to practical results.

A grain of methylene blue will do the patient no harm, even if it does color the urine. It may be of benefit in some cases. It gives us a vast field for research. I anxiously await the verdict of the critics.

I am indebted to Dr. Carroll (physician to St. Catharine's Hospital), for the clinical material which he kindly placed at my disposal.

Clinical Department.

GUAIACOL IN TYPHOID FEVER.

By B. M. BAKER, M.D.,

Norfolk, Va.

Having read in a recent copy of the New York *Herald* the experience of M. Holscher, of Mulheim, with this drug in treating sixty cases of typhoid fever, I thought perhaps some good might come from a brief account of my experience with this agent, in treating a few cases within the last few months.

Some three months ago, I had in charge a man thirty-five years of age, suffering from a mild attack of typhoid, who, after having had no abnormal temperature on the twenty-first and twenty-second days, suddenly had the temperature to go up to 100° F. at five P.M. on the twenty-third day. On questioning him, I found that ten years previous to that time he had suffered from what he termed bronchial hemorrhages, and although I found no signs of either recent or old chest trouble on physical examination, yet there was slight cough and scanty mucous expectoration, and I therefore thought it best to put him on guaiacol in five-drop doses, three times a day. After forty eight hours the temperature fell to normal, but the cough and expectoration continued. This rapid effect of the drug upon the temperature made me think at once of the possibility of its having the power of arresting the growth of the typhoid bacilli in the intestine.

Since then I have treated seven cases of typhoid with it, and my friend, Dr. C. F. Newbill, at my suggestion, has tested its efficacy in twelve other cases, making in all nineteen cases.

Most of the cases have been mild types of the disease, with few complications and no violent symptoms, and they have varied greatly in ages, from a baby of eighteen months to an old lady of sixty-five years.

As our German brother claims, we have found no need of antipyretic measures of any sort, and the temperature is kept constantly low, simply by the administration of this drug. With it the temperature falls, the pulse grows less rapid, the tympanites and diarrhœa disappear, the tongue becomes moist and clean, the nervous symptoms rapidly subside, and the patient goes on to a complete recovery. This has been proven in each of the nineteen cases treated by us.

One case, which illustrates more clearly the good effect of the drug, I will mention in brief. I was called to see Martha J——, a negro girl sixteen years of age, on the night of the sixteenth day of the disease, when I found her with a temperature of 105° F., pulse, 135, dry brown tongue, teeth covered with sordes, wildly delirious, picking at the bed clothes, etc. She had to be kept in bed by force. The abdomen was markedly tympanitic, and she was having frequent pea-soup evacuations. I ordered bismuth, brandy, and guaiacol in five-drop doses, given

in whiskey, largely diluted with water, three times a day, after eating; milk and beef-tea made up her diet. The next day the temperature had fallen two degrees, pulse less frequent and stronger, delirium less pronounced, and diarrhœa and tympanites much improved. Seven days from this time, I found the temperature normal, pulse 80, and patient convalescent. She is now perfectly well.

It seems to me that this is sufficient trial to justify further investigation of the power of the drug in controlling the fever in these cases, and I send you this mention of my experience, hoping that you will see fit to publish it, and that some of my confrères in the profession may adopt my suggestion, and after trying it, will write us the results of their experience with the drug in similar cases

September 5, 1893.

REPORT OF TWO CASES OF PLACENTA PRÆVIA, WITH ANTEPARTUM INFECTION —RECOVERY.

By CHARLES WILMOT TOWNSEND, M.D.,

NEW BRIGHTON, S.I.

CASE I.—On Monday, October 17, 1892, I was sent for by Mrs. G——, a multipara, who had previously engaged me for her confinement. On my arrival I found the patient lying upon a bed covered with blood, pulseless and cold, restlessly tossing from side to side. Her tongue was coated; temperature, 103° F. and altogether she presented a picture of extreme loss of blood conjoined with septic infection. She was of stout build, and her pendulous abdomen was enormously distended by the pregnant uterus.

On examination the fœtal heart could not be heard. The uterine contractions were weak and infrequent. A steady stream of blood trickled from the vagina; this she told me had continued for nearly a week. After a thorough disinfection of my hands I made a vaginal examination. The vagina was capacious, both anterior and posterior walls prolapsed. The cervix was high up and far back, and felt thick and sodden to the finger. It was dilated to the size of a silver dollar. Passing my finger through the cervix I felt the placenta as a soft mass blocking up the uterine opening. I acquainted the family of the serious condition I found, and having again cleansed my hands and arms I passed my hand into the vagina, rapidly dilating the cervix with my fingers. Sweeping my finger around the lower uterine segment I found that I had to deal with a centrally implanted placenta prævia. Without much effort, but with an alarming hemorrhage, I bored my way through the placenta and forced my hand into the uterus, where I found that the fœtus presented by the breech and was in the first position. After several efforts I finally found a foot extended in the fœtus axilla. Drawing it down, I proceeded to extract, and brought into view a macerated foot and leg. After strong traction the second foot was also brought down, but the body could not be delivered, and by examination I found that a much distended abdomen was the cause. I perforated this easily and allowed a quantity of light colored serum to escape. Hitching my forefinger on the pubic arch of the fœtus I delivered the woman of an ill smelling, hydrocephalic child, which had apparently been dead for some weeks. After removal of scraps of placenta and membranes, and irrigation with a 1 to 5,000 corrosive sublimate intra uterine douche, the uterus contracted fairly well. The fœtus was full term and much macerated. The liquor amnii was thick, dark colored, and of a foul smell. The placenta was of the usual size, of soft consistency, with yellow patches here and there, and did not contain much blood.

The family history of the woman is interesting. She is of Irish birth, thirty-eight years of age, and has borne her husband fifteen children. The first five were born alive, and of these two are now living. The next ten were still-born. Twice she has given birth to twins. She acknowledged that her husband had lived an irregular sexual life, and in all probability she acquired syphilis from him after the birth of her fifth child, as the children now living are healthy and strong.

The after-treatment was intra uterine corrosive sublimate, 1 to 5,000, douches three times a day, with carbolic vaginal douches every three hours. Active stimulation with hot milk, whiskey, and eggs, and compound tincture of cinchona as a tonic. Her recovery was complete.

CASE II.—Mrs. S——, an Italian woman, aged forty-three. Had had twelve children, all born alive, and eight now living. One twin birth and no miscarriages. No specific history. When summoned I found the patient much exhausted from hemorrhage, which had lasted off and on for two days. Temperature was 100° F.; pulse, 120 and feeble. She had had a few weak uterine contractions. Fœtal heart could not be heard. On examination the cervix was soft and partially dilated. The uterus was, as in the preceding case, blocked by the presence of the placenta. I dilated the cervix with my fingers, and sweeping them around within the uterus found that on the right side, high up, I could feel the head presenting in first position of vertex. Rupturing the membranes I passed my hand into the uterus, where I easily secured a firm grasp upon a foot and proceeded with the extraction of a dead female fœtus about full term. I then expressed the placenta and membranes, and douched the uterus with a hot corrosive sublimate solution of 1 to 5,000. The uterus contracted firmly. I ordered carbolized vaginal douches and stimulation with hot milk and whiskey. The next night the temperature had risen to 102° F, so I gave her intra-uterine douches of corrosive sublimate solution. First quart, 1 to 2,000; second, 1 to 4,000; third, 1 to 8,000, and finally, 1 to 16,000 every six hours She also got a tablespoonful of Epsom salts every hour till her bowels moved freely. As a tonic she took compound tincture of cinchona. Her niece, who took care of her, gave her carbolized vaginal douches every three hours. Her temperature varied from 101° to 103° F. for the next few days, but finally came down to normal, and she made an uneventful recovery.

The most noticeable features in the above cases are the large number of children the mothers had borne, and their infection prior to confinement. The women were both broken in health from frequent child-bearing and had large subinvoluted uteri before impregnation.

Their septicæmic infection can be easily accounted for, as they were neither over-cleanly in their habits, and one had bled for one week and the other for several days.

INFANT UMBILICAL HEMORRHAGE.

By ELMER E. KEISER, A.M., M.D.,

TACONY, PHILADELPHIA, PA.

HEMORRHAGE from the infant navel is a rather infrequent occurrence, and when it does happen it is generally about the time of the separation of the cord. It is also an accident which, if discovered early, should, it seems, be easily remedied, and if the loss of blood has not been too great, without mortality. In the majority of instances the termination of these casualties is a favorable one; unfortunately, however, the following case was an exception to these generalities.

Mrs K——, the wife of a laborer, was delivered of a female child after a short and easy labor. The mother and father were both of bilious temperament, and apparently healthy. There was no evidence of syphilis, and no history of hæmophilia in the family of either parent. The child, too, was seemingly healthy, although it was not disposed to make much noise. All its functions were properly performed. The cord became detached on the fifth day, and by the eighth it was entirely healed, and to all appearances was clean. On the evening of the twelfth day the mother found its dress soaked with blood, which was still flowing profusely from the navel. I was called at once, and responded promptly. Ergot was administered inter-

nally, and about ten minutes were consumed in employing vinegar, tannic acid, cold and hot water, with and without compression, but with no effect on the bleeding. The umbilicus was then completely closed with sutures placed by a very fine needle. This also failed, the blood flowing nearly as freely as before, and also through the track of the sutures. Two ligatures were now deeply inserted across the navel, at right angles to each other, and were tightly tied, but with no better success. Styptics and compression again proved ineffective. The child died about ten hours after the bleeding was first noticed.

I regret that at the beginning the umbilicus was not transfixed by needles, at right angles to each other, and a ligature thrown around them. The result might have been different, but it is doubtful. A small quantity of the blood was collected and showed no tendency to coagulate. A predisposing cause which suggests itself in this case is that the infant may have been poisoned by malaria, as the family lived on the edge of a swamp in which that miasm is rife.

PERSISTENT SINGULTUS.

By H. L. ROSENBERG, M.D.,

MENOMINEE, MICH.

In the MEDICAL RECORD of August 19th is a report of a case of "Persistent Singultus," by Dr. Gallant, and I wish to report a similar one. On June 5, 1893, A. C. M——, aged thirty-six, consulted me about a persistent singultus which had continued for forty-eight hours. I was unable to discover the cause, as it came on in the morning immediately after rising, and continued so long as he walked about. He could not eat, as deglutition provoked the difficulty. I saw somewhere a recommendation that full doses of pilocarpin be given, and I gave him a one-third-grain tablet of Wyeth's make. He was advised to go home and go to bed, which he did. Free diaphoresis occurred in a short time. He remained in bed one day, and has had no return of this distressing trouble.

GRANITE CHIP IMPACTED IN THE AUDITORY CANAL AND TYMPANIC CAVITY.

By CHARLES S. RODMAN, M.D.,

WATERBURY, CT.,

CONSULTING SURGEON TO THE WATERBURY HOSPITAL.

B. L——, a boy, aged ten, living in an adjoining town, pushed a piece of broken stone into the right auditory canal "to break a bubble" after bathing. His physician failing to remove it with a small glass syringe, he was on the same day taken to a medical man, known as an aural and nasal specialist. The latter, after vainly attempting to extract, referred the case to an able general surgeon. It was now evening and an appointment was made for the following day, when another fruitless effort was made. The extraordinary character of the incident being now apparent, it was fully set forth in the newspapers, which announced that a few days later the lad was to be operated on and the stone removed. The time arrived, surgeon, specialist, assistants, as well as a reporter of a daily paper, were assembled. The boy was etherized, and a protracted struggle for the possession of the pebble terminated unsuccessfully. The papers assured the now somewhat interested public that the stone was not doing much harm anyway, and would be left to work its own way out. According to the statement of the boy's mother and physician, it may be added that the chip of granite was visible in the ear until after this last operation, which was under ether and chiefly conducted with forceps and the light of the heavens; all of which history is thus briefly recited, not to discredit anyone's contention with an unaccustomed problem, but to show that extraction of the foreign body became a matter of difficulty; that the means successfully employed may therefore be of some value in like cases; and incidentally, that there occurred that which is always liable to happen when one not habitually using the head-mirror seeks to remove with forceps a sharp-pointed body from the auditory canal of an anæsthetized patient.

Two days afterward, on the ninth day after his unlucky bath, the boy was brought to me by his family physician. He made little complaint, although he had been restless and in some distress at night. A bloody discharge came from the auditory canal, which was swollen, leaving room only for the insertion of the probe. After cleansing and brief inspection of the ear, the lad was etherized upon a table in a dark room under a Mackenzie condenser; no foreign body could be recognized by the probe, much less by the illumination of the head-mirror. At the extremity of the canal a rough surface was felt with the probe, but so tense were the tissues and such the swelling that it was impossible to distinguish between the supposed pebble and a denuded osseous wall of the tympanum. This rough surface was so deep in the bony canal that it appeared certain that mere detachment of the auricle would not facilitate extraction of a foreign body, if present. Chiselling of the posterior wall for purposes essentially diagnostic did not seem attractive, while the writer recalled a case narrated by Pilcher, quoted by Hartmann, in which the surgeons of a London hospital looked in vain for a nail supposed to have entered the ear, and found, two days after operating, at the autopsy, that there was no foreign body at all.

Thinking that if sufficient power could be applied, the tissues other than osseous, those of the cartilaginous canal, and the semi-polypoid occluding the bony, might be compressed and the passage dilated, making it at least as accessible as after detachment of the auricle and without the annoying hemorrhage, I introduced a bivalve speculum as deeply as possible, separating the blades by turning the set screw with strong pliers. Removing the speculum, a Woakes nasal dilator was substituted and expanded *ad maximum*. After a few efforts with these instruments it became possible to recognize the existence of a foreign body, when the hook was passed above it and extraction accomplished without further delay.

The stone proved to be a fragment of granite, with sharp angles and points, one centimetre long, and weighed one-third of a gramme. The patient was dismissed, with directions to keep the ear clean with a weak saline solution. Inspection a week after showed a large perforation in the anterior-inferior quadrant of the membrana tympani, giving a loud whistle on Valsalva's experiment. The perforation soon closed and the hearing power, much impaired, is gradually increasing.

To those who work constantly with the head-mirror this case possesses little interest, except in the suggestion of forcible dilatation of the dilatable or compressible tissues of the auditory canal as a substitute for detachment of the auricle. Every physician, however, is liable to be called upon to remove a foreign body from the ear, and my experience just narrated warrants a repetition of observations, however trite.

1. With the syringe, every foreign body can be removed that is not impacted, *i.e.*, that has not been forcibly driven into the ear or that has not swollen after insertion. Like all other instruments, the syringe can be more skilfully used under the guidance of the head-mirror, but failure will rarely occur in absence of artificial illumination, provided care be taken not to drive in the foreign body with the point of the syringe, and the stream of water is forcibly directed over or under the obstruction. It should not be necessary to add that the little glass affairs of the drug-stores are not referred to in speaking of ear-syringes.

2. Forceps are unsafe and should only be used when the foreign body projects externally and is readily grasped.

3. The hook is essential after a foreign body is impacted, as by unskilful efforts to extract with forceps. The hook is unsafe in the hands of one unaccustomed to the use of the head-mirror.

4. Forcible dilatation of the cartilaginous meatus, with compression of the swollen tissues obstructing the bony canal, affords greater advantage than is secured by detachment of the auricle without chiselling of the posterior wall. It is easier, bloodless, and involves far less traumatism.

THE TREATMENT OF GONORRHŒA.

By JOHN E. WEAVER, M.D.,

ROCHESTER, N. Y.

Dr. James Porter Fiske, of New York, has given, in the Record of August 26th, a valuable treatment for gonorrhœa; but I will give one at least two points better, and that I firmly believe cannot be improved upon. 1, Instead of salt water I always prescribe clear water, as hot as can be borne, because clear water is a great germicide; 2, then I order my patient to use the injection each time after urinating, when there is little if any danger of there being gonococci present to be carried backward; 3, I order from one to three pints of the water used each time, *i.e.*, until the soreness is gone at the first injection, and about the same amount at each subsequent injection. Old practitioners will be incredulous of my claim that the soreness will disappear with one injection. I simply say test it and be convinced. Internally I give a compressed tablet made by Fraser, of New York, composed of:

R. Cubeb. pulv.	gr. j. ½
Copaiba, solid	gr. j.
Ferri sulph. exsic.	gr. ½
Ol. santali	gr. ½
Ol. gaulther.	gr. 1/10
Terebinth. laricina	gr. ½

Every three or four hours.

In the rare cases where a slight discharge remains after all acute symptoms have disappeared, due to a previous attack, taking cold, unfaithfulness to treatment and the like, injections following urination for a few days of two or three small syringefuls of fluid hydrastis (non-alcoholic extract with glycerine), ʒ j. to a pint of water, completes the cure. Cases thoroughly treated on this plan last only from a week to ten days. Give the customary precautions in regard to drink and diet.

PERSISTENT SINGULTUS RELIEVED BY LAVAGE OF STOMACH.

By P. C. COLEMAN, M.D.,

COLORADO, TEX.

The case reported in Medical Record, August 19th, by Dr. Gallant recalls a similar one coming under my observation recently, and relieved by the same means.

In consultation with two other physicians, who had been in attendance for several days, I saw patient B——, aged seventy years, but remarkably well preserved for one of his age, and had been doing manual labor regularly up to the time he was taken with hiccoughing.

The various household remedies were tried without relief, when, after several days, the physicians were called. They had used faithfully the drugs usually given in this condition—musk, ether, bromides, chloral, opium, etc.—without even temporary relief. Hiccoughing continued under profound narcotism, and when I saw the patient at expiration of ninth day he was thoroughly exhausted, and oblivious to all surroundings.

It was found upon examination that the bladder was very much distended; I introduced a catheter and drew off a large quantity of highly colored urine, when immediately hiccoughing stopped, patient resting quietly for eight or ten hours, when hiccough returned.

Tongue was covered with a very thick, spongy coat, and as dry as a bone. This fact, taken in consideration with the treatment which had been used without relief, led me to conclude that the case had its origin in the stomach.

I had recently read in some journal, where, after all other means had failed, a case was relieved by thoroughly washing out the stomach.

A stomach-tube was attached to the Allen Surgical Pump, and stomach thoroughly irrigated with warm water.

Stomach contained no food, but a quantity of dark, tenacious mucus, with patches of separated mucous membrane, some of them as large as a finger-nail, and very much thickened. Hiccoughing did not return, and patient recovered his usual health.

Dr. Gallant states that in looking over the recent literature he could find no mention of lavage in treatment of singultus, but it seemed especially fitting in cases of gastric origin.

The history of the only three cases coming under my knowledge in which lavage had been used, namely, the doctor's case, mine, and the one referred to, would seem to sustain his suggestion.

CAMPHORATED CARBOLIC ACID.

By D. E. ENGLISH, M.D.,

MILLBURN, N. J.

Doctor S. W. S. Toms's interesting article in the Medical Record for August 19, 1893, I can quite agree with. For the last four years I have been using a preparation of camphor and carbolic acid, under the name of Carbolated Camphor, made as follows: Liquefied carbolic acid, one part by weight; gum camphor, three parts by weight. When these are put together in a bottle, the result, after a short time, is a smooth, transparent, oily liquid, almost colorless when first made, changing with age to a light pink as carbolic acid does, having the odor of camphor, a burning taste when put upon the tongue, and a specific gravity of about 0.990 compared with water. This preparation is not a chemical union but a liquefaction similar to that which takes place when chloral and camphor are mixed and there is a slight excess of camphor, which may be found in the form of a few minute crystals adhering to the bottom and sides of the bottle. It remains unchanged for an indefinite time. It mixes freely with olive-oil and vaseline, and dissolves iodoform in the proportion of one to twelve, completely disguising the odor of the iodoform. It dissolves freely in alcohol, but will not mix with water or glycerine. It can be applied freely to the skin or raw surfaces without fear of cauterizing or of causing any more pain than a one-to-sixty solution of carbolic acid causes. I have used it externally, undiluted, as a general antiseptic and surgical dressing, simply saturating a piece of muslin with it and laying it over the wound or sore. The outer dressings may be taken off every day and the piece of muslin wet with the carbolated camphor without being removed, and the wound thus kept sweet and clean with very little trouble. I think I have aborted boils and cured carbuncle by injecting it around the site of the trouble as carbolic acid is sometimes used, and with less irritation than the latter causes. Mixed with carron-oil in the proportion of one to twenty I have used it with success in burns of the first and second degrees. As a domestic remedy for burns, scalds, boils, pimples, cuts, bites of insects, etc., it is excellent.

It also has great value as an internal remedy. I have used it in five cases of typhoid fever, all of which did well. In this disease I give ten to twelve drops in a capsule, every three hours, till the urine begins to show signs of carbolic-acid poisoning. This generally occurs on the third day, showing that more carbolic acid can be given in this form than in the pure form. The camphor, I think, also has a good effect in this disease. When the urine begins to be affected I increase the interval between the doses to four, five, or six hours, and continue giving the remedy till convalescence is well established. It must not be put into the capsule long before using or the capsule will be dissolved by it. After each dose water or diluted milk should be taken, to prevent a feeling of heat in the stomach. I have also found it very useful in many diseases of the stomach and intestine due to fermentation

or the action of microbes, especially in cases of foul eructations and bad breath due to fermenting food in the stomach. It is best given in capsules, as in mixtures or emulsions the taste is disagreeable.

Whether or not this preparation is Bufalini's camphorated carbolic acid I do not know. I first had my attention drawn to it by an item in the *New York Tribune* about four years ago. The proportions should be exactly as I have stated them, as a very little larger proportion of carbolic acid makes a very much more irritating compound.

Progress of Medical Science.

The Causative Agent in Influenza. — Since the epidemic of influenza of 1889–90, in Europe, many attempts have been made by bacteriologists to discover the causative agent of this disease. In the early months of 1890 the announcement was made by Dr. Julles (Vienna), claiming the discovery of an organism which was similar to Fränkel's pneumococcus, and which he considered to bear a causal relation to this disease. Klebs discovered organisms in the red blood-corpuscles of patients suffering from influenza; Seiffert, peculiar cocci in the sputa of patients, and M. Kirchner, a diplococcus, probably identical with Seiffert's, which he was able to produce in pure cultures. None of the above organisms can now be looked upon as bearing any causal relation to influenza. There yet remains the organism of Pfeiffer, which, having fulfilled the crucial test of the three postulates of Koch, may now be considered as the causative agent of this disease. From the sputum of patients cover slip preparations can be made, according to Pfeiffer, by staining the specimens in Löffler's methylene blue or in a weak watery solution of carbol fuchsin. In every specimen numerous influenza bacilli are to be found. These organisms are not quite as large as the bacilli of mouse-septicæmia; they are two or three times longer than broad; sometimes larger specimens are found, especially in pure cultures. After much difficulty and many failures in the production of cultures—for these organisms could not be grown on the ordinary cultivating media—Pfeiffer discovered that blood is necessary for the growth of the bacilli. Sterile blood was dropped on the surface of slanting agar tubes, and a drop of influenza sputum mixed with the blood. The organisms grew luxuriantly. In this way pure cultures have been obtained in abundance. Pfeiffer determined afterward that the hæmoglobin of the red blood-corpuscles is the substance which is necessary for their growth. The growth of the influenza bacillus on blood agar is very characteristic. Cultures of twenty-four hours' growth show very small colonies of light, transparent drops, which have a tendency to flow together only when many colonies lie in immediate contact. The influenza bacillus is ærobic, growing only in the presence of oxygen, and best at a temperature of 38° C.; at 43° C. its growth ceases, and at a temperature of 28° C. it grows badly. In drinking-water the organisms die rapidly. They are also very susceptible to the process of drying, which destroys them quickly. In the sputum of none but influenza patients could this organism be discovered. The bacilli were also found in all cases in the lungs of patients dying from this disease. Inasmuch as animals, as a rule, are immune to influenza, another difficulty arose in fulfilling the condition of inoculation. Mice, rats, guinea-pigs, rabbits, pigs, cats, and dogs were experimented on in turn, but none of these animals were found by Pfeiffer to be susceptible to this disease. To monkeys only could he transmit the disease. Injections of cultures into the lungs, through the chest-wall, as well as inoculations upon the mucous membrane of the nose of these animals, produced attacks of the influenza. From these experiments of Pfeiffer the causal relation of the influenza bacillus to the disease must be admitted, the three postulates of Koch having been fulfilled: 1. The influenza bacillus is to be found in all cases of influenza. 2. The organism cannot be found except in this disease. 3. With pure cultures the disease can be produced in susceptible animals (monkeys).

In conclusion it is interesting to note that Pfeiffer has isolated a form of pseudo-influenza bacillus which he has found in three cases in the broncho-pneumonia of diphtheritic children, and which, like the influenza bacillus, grows in cultures upon blood agar. A differential diagnosis is easily made through the difference in growth of the two organisms.—*Johns Hopkins Hospital Bulletin.*

Antiseptic Properties of Calomel and of Tobacco.— The eminent antiseptic properties of calomel have been again demonstrated by recent experimental researches instituted by Wysokowitch. They refer in part to the action of this medicament on bacteria in the midst of alimentary substrata, in part to its action on bacteria living in the human organism. Tuberculous guinea-pigs, and, with regard to intestinal disinfection, dogs, were especially experimented upon. It resulted from these investigations that calomel, even in minute doses, arrests the development of bacteria, eventually destroying them. Calomel solutions in 1 to 40,000 concentration also arrested the development of the anthrax bacillus and of the cholera vibrio. Experiments performed on the living organism had a somewhat different result. When administered by mouth to a healthy dog, calomel acts as a strong cathartic and engenders sanguinolent stools. But it fails to reduce sensibly the quantity of living bacteria present in the intestine; it is not an antiseptic in relation to the intestinal mucosa. It is probable that in the living organism there exist certain special conditions which prevent the antiseptic action of calomel (transformation of calomel into mercury sulphide). A similar result was obtained by the application of calomel to tuberculous dogs —the quantity of tubercle bacilli present in the muscles was not reduced by intra-muscular calomel injections. As to the antiseptic action of tobacco, Professor Tassinarini, in Rome, calls attention to the fact that as far back as in the seventeenth and eighteenth centuries the use of tobacco was recommended by many physicians as a prophylactic in times of epidemics. In 1842 Professor Ruef, in Strasburg, it is said, stated that all the workingmen employed in the Royal Tobacco Manufactory had remained exempt from contagious diseases. Recholier made the same observation in 1883, and Walter Cock, of Texas, in 1888, even recommended tobacco smoking as a preventive against tuberculosis. Dr. Vassili, of Naples, in 1888, experimented on a balloon in which a layer of gelatine was sprinkled with comma bacilli. As soon as the smoke from one to four cigars, according to the intensity of the tobacco, was introduced into the balloon, the micro-organisms of the gelatine were completely killed. These various experiments were imitated by Tassinarini, and he found that by tobacco smoke the comma bacilli, the bacilli of pest and of pneumonia are destroyed, or at least arrested in their development. In these experiments it was observed that the bacilli of cholera and of pneumonia were destroyed within a few minutes, the bacilli of pest offering more resistance, while the bacilli of typhoid fever were scarcely interfered with. Tassinarini also affirms that smoking delays caries of the teeth, for which reason women, it is alleged, are more afflicted with diseased teeth than men. All of these views, of course, should not be accepted as infallible without further demonstration—*Medical Review.*

The Physiology of Weariness.—In delivering the Rede Lecture at Cambridge, recently, Professor Michael Foster chose as his theme "Weariness." Those acquainted with Foster's works and the combined breadth and caution of his generalizations will know that no one could have been selected who was more likely to do justice to a subject which has a personal interest for every worker. Commencing with a simple muscular act, the lecturer analyzed the physiological phenomena of weari-

ness in such and in the higher work of mental operations. He clearly emphasized the two prime factors in the production of exhaustion—too rapid expenditure of capital or force and the accumulation of the products of activity in the working organ. After proving that "the nervous system was a candle which could not profitably be burned at both ends at once," Professor Foster went on to show that endurance depended largely upon "blood adequately pure," and that the readiness with which "the internal scavengers freed blood from the poison which the muscles (and other active organs) poured into it" was proportionate to the staying power of the worker. "The hunted hare died, not because he was choked for want of breath, not because his heart stood still, its store of energy having given out, but because a poisoned blood poisoned his brain and his whole body." The "humbler helpmates" of the active organism—that is, the nutritive, excretory, and metabolic functions of the body—were of the highest importance to the enduring activity of the higher executive mechanism. Professor Foster touched upon, but did not treat, the subject of "inertia or laziness," and we trust that he will on some future occasion afford us the benefit of his views upon this phase of the subject. That "unwillingness to stir" greatly increases the work of compulsory stirring is matter of constant observation, and the "labor of love," though greater than that of compulsion, may be borne with much less effort and with much less weariness than the latter.—*The Lancet.*

Cutaneous Excretion of Carbon Dioxide and of Water.—Schierbeck gives the results of some experiments he has made on the elimination through the skin of carbon dioxide and water at temperatures between 86° F. to 102° F. The person experimented on was placed in a box closed on all sides except that it had an opening through which the head protruded, and this was ventilated by a large Pettenkofer's apparatus (*The Lancet*). He was sometimes naked and sometimes clothed with thick woollen material. The excretion of carbon dioxide at temperatures between 29° and 33° C. amounted with very small variations to 0.35 gm. per hour, or about 8 gm. per twenty-four hours, the quantity discharged being independent of the clothing. If the temperature rose above 33° C. (92° F.) the elimination of carbon dioxide underwent a sudden increase, so that at about 33.5° C. it was doubled. It continued to augment with the further increase of temperature, but not with the same rapidity, up to 1.2 gm. per hour at 38.5° C., which corresponds to about 28 gm. (or 432 grains) in the twenty-four hours. As regards the excretion of water, this only consisted of insensible perspiration up to 33° C. (92° F.); but above that temperature it became sensible perspiration, or, in other words, sweating set in. The "critical point" was thus identical for the elimination both of carbon dioxide and of water. The discharge of water did not, however, show such a sudden increase as that of carbon dioxide, but rose more uniformly in accordance with the increasing temperature. It is therefore difficult to give any general statement showing the amount of water eliminated by the skin, since the temperature ordinarily varies within considerable limits.

Excretion of Urea in Certain Surgical Diseases and after Major Operations.—According to the Paris correspondent of *The Lancet*, at a meeting of the Académie des Sciences M. Lucas-Championnière presented a note on the above subject. He stated that for the last six years he has systematically estimated the quantity of urea passed by his patients before and after major operations. The diminution of urea is by no means pathognomonic of the existence of visceral cancer. That phenomenon is found especially where cancerous cachexia is present; when the general health is maintained the amount of urea remains about normal. A descent to a daily excretion of six, five, or even three grammes appears to M. Lucas Championnière to be more commonly met with in visceral than in other forms of cancer. Nevertheless, even in ovarian cancer, the proportion of urea passed daily may be about normal. This he regards as favorable to an operation, and he has found that by choosing his cases in accordance with this indication the mortality after ovariotomy for cancer has considerably diminished. But non malignant diseases of the ovary are frequently responsible for a fall in the quantity of urea excreted. This is particularly the case in sclero-cystic ovaritis, which, contrary to the usual opinion, is productive of serious cachexia. In the case of cachectic patients who are passing greatly diminished quantities of urea, it is advisable by rest and feeding to increase the daily urea before thinking of operating. But whatever the quantity of urea excreted before a major operation, from the first to the third day after it the proportion increases invariably to an extraordinary extent, the maximum being reached generally on the third, sometimes on the second, day. Be it noted that all M. Lucas-Championnière's operation cases are on low diet during that time. The urea is often doubled, and even trebled, in quantity. He has seen it increase from five to twenty-five grammes. In a few days the excretion falls to about normal and remains there in case of recovery. Thus in the case of a woman whose ovary, filled with small cysts, had been removed, the urea passed daily remained after recovery at twenty-five grammes, the quantity before operation having been seven, eight, and nine grammes at the maximum. A practical deduction to be drawn from these observations is the necessity of relieving the kidney thus suddenly burdened with unusual excretory work. Low diet and purgatives are then fully indicated, and our forefathers were justified in thus prescribing after serious operations. M. Lucas-Championniere terminates his communication by insisting upon the great importance of a careful estimation of urea passed both before and after major operations.

Subcutaneous Galvano-cautery.—Gilles proposes a new method of treatment under the name of interstitial galvano-cautery. The part to be cauterized is transfixed by a specially constructed needle, which is then made to carry a galvanic current of sufficient magnitude to heat it to any required degree (*The British Medical Journal*). The middle part of the needle is of platinum, while its ends are of copper or other good-conducting metal. Owing to its high resistance the platinum part becomes heated by the current, while the rest of the needle remains cool. Experiments made upon the lungs, the liver, the muscles, etc., of dogs and of rabbits show that living tissues can be destroyed subcutaneously without suppuration; patches of cicatricial tissue have been found post mortem in the sites of the operations. The skin punctures gave rise to no trouble in most of the cases related. It is not necessary to raise the temperature of the platinum to a high degree. Destruction is complete with a temperature of 100° C.; the current must be carefully regulated by a rheostat.

Perlèche.—M. Raymond recently showed to the Société Française de Dermatologie et de Syphilographie two children affected with this disease, which, it appears, is common in Paris primary schools (*The Lancet*). The affection is characterized by superficial ulceration of the commissure of the mouth; the epidermis swells and becomes white and a fissure of variable depth develops, this fissure is generally limited to the commissure, but it may extend to the cheek. The lesion is superficial and mostly heals spontaneously in a few weeks, but is very apt to return. Being very contagious, it will frequently spread as a veritable epidemic throughout a school. M. Raymond has constantly discovered in bacteriological examination the staphylococcus albus, but he opines that other micro-organisms may also produce the lesion. Diagnostic errors may be made in these cases, the affection being mistaken for herpes labialis or mucous patches. M. Fournier also remarked on the difficulty of distinguishing between perlèche and secondary manifestations of the syphilitic virus.

ADDISON'S DISEASE—THE FUNCTION OF THE SUPRARENAL CAPSULES.

A GREAT deal of interest has been excited of late in the function of the so-called blood-glands, viz., the thyroids, pituitary body, and suprarenal capsules. Perhaps these last-named bodies have been relatively less studied, yet physiologists have not neglected them. M. Albanese (*Archivios Italien. di Biologie*) has found neurine in the urine of individuals suffering from Addison's disease. Starting with this observation he made some experiments on frogs, and found that these animals were four times more susceptible to injections of neurine after removal of the adrenals. He concludes that these glands have some function in destroying this substance. Abelous and Langlois have found (*Compt. Rend. de la Société de Biol.*) that destruction of the adrenals in guinea-pigs, if complete, caused death by lowering of temperature and inanition. In their muscles was found a toxic substance that had a depressing effect on healthy animals. After grafting the glands into healthy rabbits, destruction of the normally situated organs did not cause death. Supino (*Archivios Italien. di Biologie*) found that removal of the adrenals in rabbits did not cause death. The blood-serum of the acapsuled animals produced, however, a paralyzing effect on frogs.

In this country, Dr. William G. Thompson has recently studied the subject of the functions of the adrenals ("Transactions of the Association of American Physicians," 1893) in connection with the pathology of Addison's disease. Adding to the exhaustive article on this latter subject by Lewin, Dr. Thompson finds that the number of cases reported up to date is seven hundred and fifty-seven. He himself reports six cases, three of them with autopsies. Dr. Thompson collects much evidence to show that in Addison's disease lesions of the adrenals are not always present. This lesion was absent, for example, in twelve per cent. of Lewin's six hundred and thirty cases. Besides this, one hundred and twelve cases of lesion of the adrenals without Addison's disease are collected. And, finally, a case is reported in which the disease was caused apparently by a destruction of the left splanchnic nerve through the pressure of an aneurism, the capsules being normal. The fact is admitted, however, that the adrenals are very susceptible to tuberculosis, and that Addison's disease is associated in about eighty per cent. of cases with tuberculosis.

Dr. Thompson has made a number of experiments upon animals, in order to determine the functional importance of the suprarenal capsules. He found that it was extremely difficult to remove them without causing serious surgical lesions. Hence he destroyed them with the cautery. Animals thus treated showed no bad after-symptoms whatever. He also found that injections of glycerine and aqueous extracts of the glands had absolutely no effect upon healthy animals. In this respect his experience is directly contrary to that of other observers. He comes to the conclusion that Addison's disease is not due to a primary lesion of the adrenals, but is more probably the result of irritation and disease of the abdominal sympathetic nerves and their ganglia.

The evidence for this conclusion is certainly very strong. On the other hand, it may be suggested that in many cases in which the adrenals were reported healthy, careful examinations were not made. Dr. Welch is authority for the statement that it is sometimes very hard to find the bacilli of tuberculosis in these organs, even though they are present. Furthermore, it is asserted by Tissoni that if animals with adrenals are kept long enough they will eventually develop pigmentation. Finally, there is, we believe, no experimental and very little pathological evidence that injury or disease of the sympathetic nerves will cause pigmentation. We feel inclined ourselves, despite the strong case made out by Dr. Thompson, to consider Addison's disease an adrenal tuberculosis. The question, however, needs further study, and we trust that in future, as Dr. Thompson suggests, a more thorough examination of the nervous system will be made in all cases of Addison's disease.

THE MALE NURSE.

WE have received from a correspondent a very pathetic account of his experiences with male nurses, trained and otherwise. The impression we gather is that all male nurses are bad, but that some are worse than others. It seems as if there were something in the character of the male nurse's work which circumscribes the intelligence, stunts the morals, and depraves the habits. According to the presentment furnished us, the most serious evils of his character are untrustworthiness and intemperateness, while the minor, yet very constant features, are expensiveness and untidy habits. The training schools for women have undoubtedly supplied to suffering humanity a class of useful workers who have admirably supplemented the physician and done a vast amount of good.

The male training-schools are as yet few, and it is too soon to say what they will accomplish. So far, it has been asserted, all the good graduates want to be doctors, while the rest add to the disrepute of their class. We do not wish to deny that there are good male nurses; we have had the pleasure of knowing some and have heard of others. We are aware, too, that the male nurse leads a life which is full of temptations and of alternate hard work and idleness, luxury and austerity. A person who is liberally paid for two months and idle for three, must possess much self-restraint in order to live soberly and correctly all the time. The most serious difficulty, however, in attempting a solution of the trained-nurse question is this: the qualifications of the nurse call, or rather are supposed to call, for a higher grade of intelligence

and education than the work and pay justifies. A man of the same educational and social status as a female trained nurse wants twice as much pay; his work does not justify this and the supply falls below the demand. We fear that the only present means of helping the matter is to select a simpler kind of material. The most essential thing in a nurse is trustworthiness, and to this we must have a fair degree of intelligence. The less education the better in the present stage of the matter.

THE STORY OF A MEDICAL COLLEGE.

The varied experiences of a medical college are told in an interesting and ingenuous manner by the trustees of one of the minor institutions of this city. The tale is published in a circular which accompanies the annual catalogue and asks for patronage and help. The college, it says, "has passed through varied stages of management, experience, and history. At its inception it was favored and controlled by politicians, whose interest survived until their discovery that a medical college was not an effective political machine. It then passed to those who conducted it as a mere money getting concern for themselves, regardless of its reputation or future, and when it no longer served their purposes the struggle began between its alumni, who sought to make it the college it should be, and those who saw in the institution a means of advertising for themselves and their productions. The latter were dominant for a time, but steadily their grasp was loosened, and a few years ago the alumni came into full management. The struggle, which before was for control, then became one for existence, but year by year the college has advanced and strengthened, not in wealth and material substance, but in position, in public esteem, in the confidence of the profession and in good results."

Here is a rich variety of corporate experience: an era of politics, an era of commercialism, an era of ill-repute, ending, we trust happily, in an era of honest educational endeavor. The story is instructive in that it tells us that a medical college is not a good political machine nor a fruitful commercial industry. As a sound educational institution alone does it seem to gain support.

APOCODEINE.

Apocodeine is a drug of which our text-books say nothing, yet it is one whose value, according to Dr. M. Guinard (*Bulletin Générale de la Thérapeutique*) is very great: In 1891 Professor Arloing stated as the result of his experiments that apocodeine was an emetic and had properties resembling those of apomorphine. Dr. William Murrell, in the same year, is reported to have found it to act as an expectorant in doses about double those of apomorphine. Dr. Guinard, however, after a number of experiments comes to the conclusion that it is not an emetic, but possesses soporific powers like those of codeine and morphine. Given in large doses, viz., gr. $\frac{1}{2}$ per pound of animal, hypodermically, it causes violent nervous excitement and convulsions. It is not very toxic, however, and in doses of gr $\frac{1}{4}$ per pound it has calmative effects Professor Fröhner (*Monats. f. prakt. Thierheilk.*) has also found that it is not an emetic.

M. Guinard is of opinion that codeine is not a very safe drug, and cites in support of this view the authority of M. Laborde. This gentleman states that codeine ought to be employed with extreme caution on account of its insidious toxic action. According to Guinard, apocodeine acts more upon glandular secretion than does codeine, it produces a quieter and more restful sleep, and does not, like codeine, have unpleasant effects upon the vascular apparatus. Neither has it so much of the convulsive properties. It is, in fine, not so toxic, yet it is more hypnotic.

From all these facts, based mainly, it must be said, upon experiments with animals, Guinard gives to apocodeine a much greater field of usefulness than to codeine. Unfortunately the drug is at present altogether too expensive for every-day use. If it were not for this fact Dr. Guinard would strongly recommend its use. We regret that the experimenter's funds did not allow him to make further practical tests. For if there is a drug which is really better than one so useful as codeine, humanity must have it.

INVESTIGATING THE CORONER SYSTEM.

The medical profession will experience keen satisfaction in finding that the coroners' office and the coroner system of this city are being investigated and their shortcomings brought to the public's attention. That which the most earnest and experienced members of the medical and legal profession could not do seems to have been accomplished in a day by "Bowery Annie." The tale runs that the direct cause of the present investigation was a postal card which Emanuel W. Bloomingdale, foreman of the Grand Jury, received from Frances Weyland, who is known in the vicinity of Chatham Square as "Bowery Annie." The writer complained that she had been a prisoner in the House of Detention since July 8th last, awaiting an opportunity to testify in the case against Samuel Mills, and that although two grand juries had met since that time, no indictment had been found against Mills. Miss Weyland ended her complaint with the query:

"How long do you propose to keep me a prisoner here, without proper clothing, through no fault of my own?"

The communication surprised Foreman Bloomingdale, and he sent for the District-Attorney, who immediately began an investigation. The outcome has, so far, been to show the defects and evils of the coroner's system in a very striking light.

One of the daily papers has put the matter very justly. It is generally recognized, says the *Herald*, in the city that the present coroners are no worse than their predecessors, and that to press the investigation against individuals will do little good. The system is to blame, a system that lodges in the hands of untrained men extensive judicial powers and provides a grotesque jury system for purposes that could be better served by a single qualified official. Attention has also been called again and again to the fact that under the present tyrannical system of local politics a coroner is not always in a position to remove his subordinates without the consent of "the boss." The coroners' office is simply a political bureau, and the fitness of a candidate for coroner plays no part in his nomination.

The Coroners' Court has a degraded status in the pub-

lic estimation, and politicians regard it as a place of no consequence except for what there is in it in the way of salary and unofficial perquisites.

And the worst part of it all is the jury system. The coroners' messengers, who are generally political heelers of limited education and no special capacity, have entire charge of the work of selecting juries. When the coroner wants a jury he gives his messenger a lot of blank subpœnas and sends him out to scour the neighborhood for jurors. The messenger can summon whoever he pleases. There is no check on him whatever. None of the coroners deny this. It is the common practice, and has been for many years. The value of a verdict rendered by such a jury, and the probability of getting just results out of such a system, can be easily estimated.

But the coroner is provided for in the State constitution, and to make a change necessitates an amendment of the constitution. Fortunately, delegates to a constitutional convention are about to be elected, and it is believed that the long-needed reform will be effected.

GOVERNOR HOGG AND THE "BOO!!"

The Texas Health Journal says editorially: "We give the following, clipped from the *Dallas News*, in evidence:

"'GAINESVILLE, TEX., August 4th.—William Parnell, confined in the county jail for insanity, was found dead in his cell this morning. Parnell was arrested on the streets here about six months ago in a wild and almost uncontrollable condition, but after a few days' confinement he become docile and was carried to the county farm. Last Monday he became frantic and tried to kill everybody in sight. He was brought back and lodged in jail, refusing to eat anything until yesterday, when he ate a light dinner. Parnell was afflicted with a loathsome disease, but this fact was not known to the officers until it was discovered at the inquest held by Justice Hill today. One ear, his eyes, and a portion of one hand had been eaten away by rats when he was found. He was buried in Potter's Field.'"

The Journal adds: "That a human being, insane for six months, should be kept on the poor farm and in jail, and finally die, without a diagnosis being made, and be eaten up by rats, is a foul blot upon the fair name of Texas and a disgrace to any civilized people. The cause for this inhuman treatment is traceable directly to the refusal of the Governor to permit the additional buildings to the insane asylums of the State, after the appropriations for the same had been allowed by the Legislature. The blood of the insane people will be upon Governor Hogg, who refused them a home by vetoing the appropriation after the adjournment of the Legislature. And yet some good people think Hogg a good man. Boo!!"

We trust that the *Dallas News* exaggerates a little. Nothing, however, could exaggerate or increase the directness, simplicity, and force of the terminal editorial comment upon the Texas Governor. When Hogg finds that the *Health Journal* has cried "Boo!!" he will, we are sure, begin to look around a bit, and, having sized himself up, he will see that he and the Texas insane asylums need attention. There is a mighty power in ejaculatory language. Sin and vice, neglect and cruelty, are not much affected by the propositions of logic, but they shrink away into darkness at the sound of an apt imprecation. Why should not Texas insane asylums be reformed by a simple "Boo!!"?

THE DOCTOR AND HIS DUTY.

OUR interesting and progressive contemporary *The Medical News* is a little impatient with the faults of this imperfect world, from orthœpy to sanitation. It spells iodide without the "e," and it wants medical societies and congresses to do less "scientific work" and more preventive medicine. It deplores the fact, as we all do, that in Philadelphia there occur every year two thousand unnecessary deaths. It wants purer milk and fewer quacks and less phthisis. We extend our sympathies to our contemporary, but beg that some patience be exercised toward the backwardness of humankind, particularly the medical men. The business of the physician, after all, is that of studying and treating disease and alleviating suffering. The doctor cannot be also a professional sanitarian. He has his work to do, and he does not owe it to society to turn his energies into unremunerative and thankless channels. When society has learned that it is worth its while to prevent disease and makes work in this line an object of commercial value as well as of philanthropic ambition, then the doctor will be very much more interested in sewage and CO_2. Society is learning a little more of its obligations every year. Meanwhile the doctor is most concerned in how to treat phthisis and typhoid and diphtheria; and it is very proper that he should write about these subjects, experiment upon them, and contribute scientific articles which bear upon his daily work. The subject of drains, cesspools, canned food, wall-papers, quarantine, and the hygienic life belong to another specialty.

THE RESPONSIBILITY OF MEDICAL EDITORS.

THERE is no disposition on our part to put forth a claim of superiority in proof-reading, or in powers of detecting error, or to suggest that they never creep into the MEDICAL RECORD. Our attention has, however, so often of late been called to mistakes in the pages of some of our exchanges, that the responsibility of medical editors who permit them becomes a matter of some importance. The metric system has not yet been long enough in general use, and has too recently been adopted in the medical schools, not to expect occasional errors from its employment in prescription writing. It is because of this very lack of knowledge on the part of many practitioners that the journalist should exercise the greater care not to print anything that might be copied and prescribed to the injury of the patient. The other day we read that fifty centigrammes of corrosive sublimate were to be given hypodermically. Now, a centigramme sounds like a small amount, but fifty of them make five decigrammes, and five decigrammes are equal to half a gramme, and half a gramme is nearly eight grains, and eight grains is a large dose—even of corrosive sublimate; and we have seen equally heroic doses of stronger remedies advocated in type.

When we look at the other side of the question, much that is ludicrous confronts us. To give a single instance of many recent ones in point, a journal advises its readers to inject into the bladder from one to six centigrammes of a

solution of iodoform for cystitis. Looking up the original article, we find that cubic centimetres was what the author wrote.

Now, one centigramme of mild fluid wouldn't work any injury in a bladder, nor does it do any harm if readers are informed that experiments have been carried out upon sea-pigs—as one man translates *meerschwein*. It is also not a very serious matter if readers are informed of the benefits to be derived from applying "warm water in which a little washing water has been dissolved," or if a surgeon writes that he "ceased the artery with forceps," and the printer prints it so, when the evident intention was to indicate that the artery was seized; but when the busy practitioner is informed that he can order eight decigrammes of atropia dissolved in twenty grammes of water, and give this in increasing doses to children with enuresis, the question comes up whether the scribe or the prescriber should be held responsible for results.

News of the Week.

The Small-pox Case and the Vanderbilt Clinic.—Professor George Henry Fox writes: "In your last issue occurs a repetition of the story that two young physicians, who were pupils at the Vanderbilt Clinic, were stricken with small-pox as a result of a clinical lecture on a supposed case of varicella. The facts are as follows: A case of small-pox came to the Skin Department of the Vanderbilt Clinic on September 4th. Two competent assistants were in charge. In accordance with printed rules one took the patient over to Roosevelt Hospital, believing the case to be one of small-pox. Had the diagnosis of chicken-pox been made the patient would have been prescribed for then and there as usual. Unfortunately one of about four doctors who saw the case at the Vanderbilt Clinic, and a house-physician who examined the case at Roosevelt, contracted the disease. But they were not pupils, there was no clinic held, and the lecturers of the Skin Department were a thousand miles away."

[We give place to this correction with pleasure, and are glad to hear that neither the professors nor clinic are to blame in the premises.—Ed.]

Calendar of Discovery of Instruments of Precision.—The stethoscope, in 1816, by Laennec; the clinical thermometer (perfected), in 1850; the ophthalmoscope, in 1851, by Helmholtz; the laryngoscope, in 1851, by Avery; the sphygmograph, in 1863, by Marey.

Passage of a Thermometer through the Alimentary Canal.—The swallowing of a clinical thermometer by an insane patient at Besançon, recently, was not without its usefulness. The thermometer, a self-registering one, was entirely of glass and 113 mm. long. No disturbance was noticed, and nine days later it was passed at the anus. The scale registered a maximum temperature of 38.7° Centigrade, but a subsequent verification of the instrument reduced this to 38.1°. The axillary temperature, which had been taken twice a day during the passage of the thermometer, was never higher than 37.2° Centigrade.

Bequests to Charities.—By the will of the late Hamilton Fish, St. Luke's Hospital receives $5,000, and Bellevue Hospital Training School for Nurses, $2,000.

The Hospital Accommodations of our Great Cities.—New York has 11,000 hospital beds; Philadelphia, 6,391; Chicago, 4,684; Cincinnati, 3,000; St. Louis, 2,086; Brooklyn, 2,000; Buffalo, 1,025; Denver, 961; St. Joseph, 849; Detroit, 672; Milwaukee, 667; Omaha, 617; St. Paul, 522; Kansas City, 516; Albany, 447; and Minneapolis, 325.

The Number of Journals on medical and closely allied topics, as shown by the *Index Medicus*, is 1,119.

The Crowning Glory of the modern surgeon is to have a proprietary antiseptic named after him.

Cleveland, O., has two medical colleges, viz., the Medical Department of Western Reserve University and the Medical Department of Wooster University. Recently a cyclone has been toying with both these institutions and there have been resignations and appointments in such number and rapid sequence that we cannot pretend to say where these institutions are now at. The atmosphere is clearing, however, and the *Medical Gazette* predicts a prosperous and useful career for all parties.

Imported Beer.—*The Lancet* analyst finds salicylic acid in a very popular brand of imported beer. The question is suggested whether all imported bottled beers do not contain some of this drug.

The Death of Surgeon-Major Parke is announced. Dr. Parke was best known as surgeon to the Stanley expedition. He was only thirty-five years old.

Antisepticism and Edinburgh Surgery.—Dr. George Emerson Brewer writes a letter to the New York Medical Record "On Medical Study in Edinburgh." The criticism throughout is couched in most kindly and complimentary terms, with one exception. It is alleged that "with one or, possibly, two exceptions the surgeons of Edinburgh utterly fail to appreciate the advantages to be gained by the application of aseptic methods of wound treatment, now so generally practised by surgeons throughout the civilized world, or if they appreciate the advantages they fail to give their patients the benefit of them." He subsequently goes with some detail into the alleged want of care in excluding sepsis on the part of the surgeon, the nurses, or the assistants. This is a serious charge to bring against a school in which Sir Joseph Lister spent some years in developing the antiseptic system, which he first adopted in Glasgow. We mention the letter because it is important that such statements should not be allowed to pass unnoticed, and especially without the attention of those concerned being called to the matter.—*The Lancet.*

Death Caused by Lightning in France.—Statistics are before us, according to which the average number of deaths caused by lightning in France, between 1835 and 1883, amounted to 100 annually. From one year to another, however, the number of victims is very variable. In 1874, for example, there were as many as 178, while in 1843 there were only 48. The number of those struck, but not fatally, is about five times greater on an average than those killed outright.—*The Lancet.*

West Virginia Medical Society.—Officers for 1893: *President*, Dr. R. W. Hazlett, of Wheeling; *Secretary*, Dr. D. Mayer, of Charleston. Berkeley Springs will be the next place of meeting.

The Board of Medical Examiners of the State of Washington have done away with the practice of issuing temporary licenses to physicians coming to the State during the time between the regular meetings of the board. It has been found that they are not legal documents, and that the Board has no authority to issue permits to practise to anyone who has not first passed the required examination. Examinations are held on the first Monday in January and of July. The coming meeting will be held in Seattle. The Secretary of the Board, Dr. Howard Keylor, of Walla Walla, will give any information desired relative to the time and place of meetings, requirements, etc.

The Naval Post-graduate School at Brooklyn.—The following-named officers have been appointed to have charge of the new school of instruction for surgeons at the Naval Laboratory at Brooklyn: Medical Director J. H. Clark, President; Medical Inspector C. H. White, and Surgeons J. L. Neilson and M. F. Gates. The latter will serve as recorder. The school opened about August 1st, beginning with a class of two scholars, who had recently entered the naval service. The course of instruction will continue three months or longer. The following will be among the subjects of study: Chemistry, hygiene, microscopy, bacteriology, ventilation, life-saving, anthropology, and bedside work. The students will have opportunities to visit different naval hospitals and view practically the medical conditions of naval life, hospital establishments on shore and on shipboard, and the causes of diseases among sailors.

Dr. Frank E. Waxham, of Chicago, has been elected to the Chair of Laryngology and Clinical Medicine in the Gross Medical College of Denver.

The Protestant Hospital Association of Duluth, Minn., capital $50,000, has been incorporated.

Denver and its Diseases.—Denver, Col., has about one hundred and twenty thousand inhabitants and four hundred doctors, or one to every three hundred persons. The diseases that prevail there differ somewhat from those prevalent in Eastern communities; typhoid fever is at present of quite rare occurrence, having been practically eradicated by the sanitary measures inaugurated two years ago by the lamented Dr. Henry K. Steele; acute rheumatism is of infrequent occurrence; the diarrhœal diseases of children are seldom observed, except to a very limited extent in July and August; diphtheria and scarlet fever are slightly less prevalent than in other communities and decidedly less fatal. On the other hand, tubercular diseases are extremely common, the patients, of course, with few exceptions, being persons who come to this region from other parts of the country on account of lung disease. A fair estimate of the population of Denver shows that fully twenty-five per cent. of the people living here came on account of consumption in themselves or members of their families. The number of cases of cured or retarded consumption is enormous; at least ten physicians residing within two blocks of the writer were formerly consumptive, but are now in comparatively good health and engaged in active practice. Surgical practice in Denver is remarkable for the small number of acute cases—gunshot and stab wounds excepted—a deficiency which is readily explained by the absence of manufacturing industries, by the level surface of the country, the mild winters and consequent absence of icy streets, and by the light traffic on railroads and ample space and trackage in railroad yards. These favorable conditions are most unusual in large communities, and their existence here results in a wonderful immunity from accidents and surgical emergencies.—*Denver Medical Times.*

Increase of the Itch.—Dr. H. W. Stellwagon calls attention (*Medical News*) to the unpleasant fact that scabies is increasing in frequency in this country. This fact was noted, so far as Boston is concerned, three years ago by Dr. J. C. White. The disease has increased in frequency from 0.9 per cent. of all skin cases, in 1890, to 5.39 per cent. in 1891. It is most prevalent apparently in Philadelphia, a town whose increasing motor restlessness of late years may be in a measure accounted for by this interesting dermatological fact. After Philadelphia come Boston (7.38 per cent.), New York (6.36 per cent.), Baltimore (4.61 per cent.), Chicago (3.53 per cent.), and St. Louis (2.88 per cent.). Evidently the *acarus* is following the star of empire westward but slowly. It must be humiliating to Chicago to find itself so near the foot of the list. The increase of scabies is attributed by Dr. Stellwagon to unclean immigration.

Gift to a Hospital.—St. Luke's Hospital, Detroit, will receive $200,000 as a bequest from the late Samuel B. Coyle of that city.

Professor Helmholtz.—Professor Knapp has invited Professor Helmholtz to address the students of the College of Physicians and Surgeons on Tuesday, October 3d, at 3 P.M., in the upper lecture room of the college. Members of the profession who may desire to see and hear this distinguished man will be cordially welcomed.

Obituary.

WALTER VOUGHT, M.D.,

NEW YORK.

Dr. Walter Vought died at the New York Hospital, of typhoid fever, after an illness of five weeks, on Sunday, September 24th. The disease had taken a severe course from the outset, and toward the close it was complicated by pneumonia.

Dr. Vought was thirty-one years of age, and had had great success for a man of his years. He was graduated from the Yale Sheffield Scientific School in 1882, and from the College of Physicians and Surgeons in 1885. He served as an interne on the Medical Division of New York Hospital and completed his education in Heidelberg and Vienna. On commencing practice in this city, at 12 West Tenth Street, he connected himself with the Medical Department of the Vanderbilt Clinic, and at the time of his death he was one of the most active and valuable assistants there. He was also for a year Chief of Clinic in the Nervous Department, a position which his skill in organization and his ability as a keen diagnostician enabled him to fill in a most admirable manner. Dr. Vought was a most earnest and faithful worker, eager and enthusiastic in his profession, with great powers of concentration and quick decision, and that ready tact which insures success. His reputation was already attained when he was cut off in his prime.

He had at first intended to confine his work to the specialty of nervous diseases, but finding this too narrow he abandoned this plan and preferred the variety afforded by general medicine. Yet he was never superficial in his work. Few men were more careful students of medical literature; few were more closely devoted to clinical

study. The practical side of medicine was always in his mind, and the devotion of his patients, both poor and rich, attested his kindness and his skill. Dr. Vought served as chief physician at Fire Island last year at the time of the cholera invasion. By his organizing genius he was able to bring order out of chaos, to control and reassure a most unruly crowd of alarmed people, to command their confidence and respect, to arrange for their proper care under very trying circumstances, and to do much to protect the public. His efforts were appreciated and publicly commended both by the Governor and the Quarantine Commission, and also by physicians who knew how hard he had to work to accomplish the proper results.

Dr. Vought made several contributions of much value to nervous diseases, and recently published a little book on cholera which has been highly commended by the medical press. As a man he was genial, agreeable, and refined, a most charming companion and a faithful friend. There are few young physicians in this city whose loss will be so widely mourned.

Society Reports.

Pan-American Medical Congress.

First Meeting, Held at Washington, D.C., September 5, 6, 7, and 8, 1893.

(Special Report to the MEDICAL RECORD.)

(Continued from p. 411.)

SECTION ON HYGIENE, CLIMATOLOGY, AND DEMOGRAPHY.

ALBERT L. GIHON, M.D., MEDICAL DIRECTOR, U. S. N., WASHINGTON, PRESIDENT, IN THE CHAIR; ENGLISH SECRETARY, PETER H. BRYCE, M.D., TORONTO, CANADA; SPANISH SECRETARY, PEDRO JOSÉ SALICRUP, M.D., NEW YORK CITY.

FIRST DAY, TUESDAY, SEPTEMBER 5TH.

On Sanitary Motes and Beams was the title of the address by MEDICAL DIRECTOR ALBERT L. GIHON.

The health of a nation is a national consideration involving international co-operation. There should be no priority nor clash of sectional interests. State lines are not respected by epidemic intruders. No State barrier can be so defensive and impenetrable that the toxiferous germ cannot pass through. The precise form of administration may be left to legislation, the indispensable requisites being that it shall be national, that it shall have parity of voice and reasoning in the national councils, that it shall have independent executive authority under the limitations common to other departments, and that it shall be entrusted to educated and experienced medical men, who alone are competent to assume its responsibilities.

He then took up preventable disease-germs, dust, and the many death-dealing agencies that daily menace public health. A bacteriologist had found no less than thirteen colonies of germs on a single bank-note. Referring to cholera, he quoted Dr. Ernest Hart, of the British Medical Association, now here, who says "Cholera can only be drunk and eaten." Air and sunshine, Dr. Gihon styled "royal germicides."

PROFESSOR CORNELIUS G. COMEGYS, of Cincinnati, O., read a paper "On the Proper Status of the Medical Profession in the Government of Nations."

In the absence of Surgeon Estrada, of Cuba, his paper, in Spanish, "On the Sanitary Organization of the Spanish Army," was read by Dr. Pedro J. Salicrup, of New York, the Spanish Secretary of the Section.

Owing to the absence of Surgeon-General Walter Wyman, U. S. Marine Hospital Service, his paper "On National Quarantine," was not read.

Later a general discussion was in order on a motion for the establishment of a State Department of Medicine. Speakers from all over the Union expressed themselves, pro and con. The desirability of national supervision was not questioned. As a result of over an hour's debate the motion gave way to an amendment, which was carried—one in harmony with Dr. Gihon's views. It was as follows:

"It is the opinion of the members of this Section that the interests of public health should be entrusted, in every country, to a Department of Public Health, national in character, having independent executive authority, managed and controlled by educated and experienced medical men."

DR. HOPKINS, of Georgia, moved that it was the duty of every State not having such, to enact laws providing for a State Board of Health. Carried. The meeting then adjourned.

SECOND DAY, WEDNESDAY, SEPTEMBER 6TH—MORNING SESSION.

The Climatology of Egypt, a paper by DR. GRANT BEY, of Cairo, Egypt, was a lengthy and highly instructive one. He referred to its earliest geological times, taking the age of the earth, as estimated by geologists, as six million years. In support of his views he quoted Sir William Dawson, of Montreal, Canada, whose examination of the earliest rocks and fossil trees—such as palms—indicated a tropical climate in that long past, a climate such as obtains in the Soudan to-day. He accounted for the fossil trees by stating that they had been buried in the earth and sand, and were glued together by silica—hence petrified trees.

The Nile, and the Blue and White Nile, were referred to. The Blue Nile in earlier ages lost itself in the sands of the old Isthmus.

He then traced the geology and climate of Egypt back some twenty thousand years, or to a time, when the waters of the Red Sea and the Mediterranean met. At that time the Nile was a mere fiord. He went back four thousand nine hundred years in the history of Egypt, considering its rain, and rainless regions as important factors in climatology. The people that hewed the Sphinx and built the Pyramids were referred to as well.

An early day sanitarian was Mena. He changed the course of the Nile, making the coastal country less malarious, and inhabitable. Irrigation he dates back three thousand five hundred years. By early foresight some of the islands of the coast were made inhabitable. He deemed embalming an admirable sanitary measure, one instituted under Pharaoh for rendering the dead harmless.

Inundations by the Nile were many. Rock hieroglyphics recorded one where its waters rose twenty-seven feet. The warm climate of Egypt in those days was favorable to the propagation of disease. Pharaoh the Third changed the climate by making a fresh water sea in the desert. A canal led the surplus waters of the Nile to a depression in the sands. This, when filled, led to a modification of the climate, profuse vegetation, and a rainfall over what had been a waste of sand and a hitherto rainless section. This went on to the time of the Romans, or A.D. 78. Where new lakes were created, it produced a new rainfall.

At the present time French, English, and American engineers are studying the Nile. This river makes the equatorial regions of Egypt inhabitable. Reclaiming the delta of the Nile was a very gradual process. The draining is still going on. The Nile is an outlet for Abyssinia and Central Africa.

The rainfall of Egypt is ten to twelve inches annually. It has its rainless regions as well as those where the rainfall fully equals that in the tropics. In A.D. 535 there was a flood. In 548 the sea broke in, destroying the towns, and again left a swampy, unhealthy shore. To-day it has a scanty population. In 1801 the sea was let in purposely, for strategical purposes, and destroyed the environment of Alexandria, and left it an unhealthy place.

The Isthmus of Suez has an influence on the climate of

Egypt. The Bitter and Suez Lakes, and the opening of the Suez Canal, have increased the rainfall of Egypt.

Dr. Grant Bey's paper was deemed so interesting that, on motion, it was accorded extra time. He concluded amid warm applause.

"The Climates of the Santa Cruz Mountains," by Dr. James Henry Clarke, of Jamaica, B. W. I., was read by title, Dr. Clarke not being present.

"Les Mesures prophylactiques contre les Epidémies," by Dr. J. B. Lacerda, Brazil, was read by title, the author not being present.

The Climate of Jamaica.—The Honorable Dr. Cecil A. Phillippo, President of the Legislative Council of Jamaica, B. W. I., read a paper on this subject. He gave the location of the island in the Caribbean—six days from New York City—and three and a half from Tampa, Fla. He outlined its coasts, foot-hills, and mountains. Its several climates and their productions were fully described. While the lowlands were purely tropical, at Newcastle, a village in the mountains, blankets were needed at night. He pictured the facility with which the inhabitants of Jamaica could change their climate in a few hours.

Xaymaca was an Indian word, meaning a Land of Wood and Water. The several seasons and temperatures were fully explained; the sanitaria and mineral springs, also.

Dr. Wolfred Nelson, of New York City, followed with a paper on the "Three Climates of Jamaica." Its coast or tropical climate, its temperate climate, and its cold climate. He referred to the old and accurate division of the climates of Jamaica by the Spanish discoverers. It was an accurate division, and, like all truths, improvement was impossible. Its desirability as a winter climate for Americans was enlarged upon, as well as its nearness to New York.

In the three climates of Jamaica the traveller for health or pleasure will find any temperature that may please him. From a coast climate of 80° to one of 54° in the mountains.

Dr. Nelson quoted Dr. Stern, of Jamaica, Dr. Lincoln and Dr. William Osler, on climates, and included Dr. Thomas L. Stedman's article in part, on "Jamaica," or that in Buck's "Reference Handbook of the Medical Sciences." Dr. Stedman has written on the mineral springs of the island, as well as all the climatic advantages it possesses.

For certain classes of selected patients, Jamaica promises to be a new Spring of Health. The rheumatic and gouty at the mineral springs will find curative waters whose fame dates back over a hundred years. Pulmonary cases will find a soft, balmy climate, where nearly every day may be spent out of doors, that is, between November and April, or the tourist season.

The beauty and grandeur of the scenery were not forgotten.

Certain it is, Americans have a new spa at their own portals, with a variety of climates. There the nervous and overworked will find rest and cure. It is a paradise for neurasthenics. Liver and kidney cases will be benefited.

Afternoon Session.

The first paper read was on the "Necessary Laws that Should be Enacted by the Several States, by which Municipal Health Authorities may be Enabled to Control Infectious Diseases." The above, with the general trend of the papers in the section, led to a lengthy and highly instructive debate on epidemics, introduction of foreign disease, etc. Dr. Shakespeare, of Philadelphia, author of the recent classic on cholera, Dr. Cyrus Edson, of New York, and Dr. Lee, of the Pennsylvania Board of Health, were among the leading speakers. The question was fully discussed in all its phases—its effects on commerce, etc.

Dr. Cyrus Edson was in favor of stopping immigration from European ports that were known to be infected. He does not believe it possible to maintain a successful quarantine against cholera. He considers the house-fly as an active agent in spreading cholera.

Dr. Albert L. Gihon, U. S. N., President of the Section, suggested that Drs. Shakespeare, Edson, and Lee be named to draft a resolution that would embody their views as well as the views of the section. The result was the following, moved by Dr. Shakespeare, seconded by Dr. Lee:

Resolved, That it is the sense of this section, that in view of the prevalence of Asiatic cholera in Europe at the present time, and the constantly increasing number of foci of infection, immigration from European countries in which cholera exists should be temporarily suspended, as this action affords, in our opinion, the only certain means of averting a threatened invasion by the disease of the countries of the American Continent.

Be it further *Resolved*, That the resolution be reported to the General Session of the Pan-American Medical Congress, with a request for its adoption and speedy transmission to the Executives of the several countries officially represented therein.

Section in Laryngology.

Third Day, Thursday, September 7th.

The Ultimate Prognosis in Neglected Adenoid Hypertrophy was the title of a paper by Dr. D. Bryson Delavan, of New York City. The question was asked, Does adenoid hypertrophy, if left to itself, disappear, leaving the vault in a normal healthy condition? Generally speaking, it does not, but remains under some pathological state, which may continue throughout the life of the patient.

1. The enlargement may not subside, and a degree of hypertrophy sufficient to cause serious injury and annoyance may continue to exist for many years.

2. The so-called "Thornwaldt's Disease" appears to be nothing more than neglected adenoid hypertrophy.

3. Disappearance of the hypertrophy may be attended with an atrophic condition of the vault of the pharynx the result of which is a pathological state detrimental to the patient and difficult to cure.

The above conditions may influence not only the locality in which they arise, but may have far-reaching and disastrous effects upon other organs. The ultimate prognosis as to the local condition, therefore, in cases of neglected adenoid hypertrophy, is unfavorable.

Dr. Price Brown, of Toronto, inquired whether there was a preponderance of adenoids in males or females, and whether heredity was or was not a factor in these cases. He himself had seen the disease more frequently in males.

Dr. Delavan thought that the sexes suffered alike and that heredity was an undoubted factor. Children inherit either adenoids or an underlying rheumatic, syphilitic, or tubercular diathesis which predispose to lymphoid hypertrophy. The disease is more common in damp and exposed regions, but may occur in dry mountainous climates.

Effects on the Vocal Organs of Improper Methods of Singing.—Dr. H. Holbrook Curtiss, of New York City, read a paper with this title, in which the various methods of vocalization were described as taught by various singing-masters at the present time. The various methods of respiration and modes of voice-production were described at length. The writer did not believe that photography of the larynx ever showed the cords in a position of normal phonation. Even the alteration in the anatomical relations of the parts produced by the simple introduction of the laryngeal mirror was sufficient to prevent the cords from taking the true physiological position required for the normal voice. The infra-costal-diaphragmatic method is the proper one for breathing. The thyroid cartilage is depressed and the trachea made more tense

from the fact that in this mode of breathing the pulmonary apices are inflated to their maximum. The proper vocal exercises will cure many of the simpler hyperæmic laryngeal conditions. They really form a sort of massage of the laryngeal muscles.

Aspergillus Mycosis of the Maxillary Sinus.—Dr. John N. Mackenzie, of Baltimore, read the paper. (See previous report of the case in *Johns Hopkins Hospital Bulletin*, November, 1892, and "Transactions of the American Laryngological Association for 1893.")

Hysterical Aphonia and Deafness was the title of a paper by the Chairman of the Section, Dr. E. Fletcher Ingalls, of Chicago. Hysterical deafness is comparatively rare. I find reports of a few cases, but have never met with it myself excepting in a single instance, a brief history of which I think will be of interest to this Congress. The case is that of a woman, aged twenty-three, and a teacher by profession, who recently came to America from Ceylon. She had been annoyed for three years by weakness of the voice, and sometimes by complete aphonia. About two years ago, while making an ocean voyage, she was greatly alarmed by a rat springing upon her. Immediately thereafter she lost the sense of hearing, and since that time has been so deaf that she could not hear ordinary conversation, and could only understand when addressed in very loud tones with the person's lips close to her ear. She had been slightly deaf before the fright, but the symptom was greatly increased immediately afterward.

When she came to see me, in the early part of July, 1893, she was still extremely nervous, and complained of dryness of the throat, inability to speak excepting in a whisper, and deafness so great as to require shouting to enable her to hear. Her general health was good; there was no history of predisposition to disease; pulse, 100; temperature, 100° F.; no cough nor expectoration; appetite fair and digestion normal. The hearing, tested by an ordinary watch, showed that no sounds whatever were appreciated even when the watch was placed in contact with the ear or temporal bones. The left membrana tympani was considerably thickened; the right normal. There was no congestion of the larynx, and the cords were well approximated on attempted phonation, but this position could not be maintained. She talked only in a whisper, but upon directing her to sound the letter *a*, while examining her larynx I found that she could easily produce loud sounds. I applied a mild astringent spray to the larynx, and a spray of menthol, five grains to the ounce, to the Eustachian tubes, through the naso-pharynx, the application being made by a long-tipped Davidson's No. 59 atomizer, which was introduced back of the palate, the spray being driven in with an air-pressure of fifteen pounds, while the nostrils were tightly held.

She was given internally berberin muriate gr. j., ext. of valerian gr. ij., and sulphate of strychnine in doses of $\frac{1}{20}$ of a gr., which I proposed to increase rapidly to $\frac{1}{10}$ or even $\frac{1}{8}$ of a grain.

Three days later it was noted that she felt something better, stating that there was a "softening" in the ears, and seven days after the first treatment her friends stated that she occasionally spoke aloud, and her hearing was improved. Strychnia was now increased to $\frac{1}{10}$ grain dose without appreciable physiological effect. Continuance of the treatment along this line, with electrical application and topical use of menthol, promise a complete cure.

Dr. Merrick, of Baltimore, thought that the length of time required to obtain the good results in Dr. Ingall's case threw doubt on the correctness of diagnosis as to the case being purely hysterical.

Dr. Curtiss, of New York, had seen deafness in hysterical aphonia, but had not suspected a relation of cause and effect between the two, but the cure of the aphonia had been followed by great relief to the deafness.

Dr. James E. Logan, of Kansas City, gave the history of a case of hysterical aphonia, with thickening of the ventricular bands. He had thought that this latter was due to the vicarious action of the bands in the act of phonation.

Dr. Curtiss thought that the ventricular bands were always thickened in hysterical aphonia, but did not believe it possible to approximate these bands by voluntary effort. He would therefore doubt their vicarious action, believing rather that the thickening caused the aphonia.

Dr. Price Brown inquired as to the possible danger of cumulative action from the dosage of strychnine given by Dr. Ingalls.

Dr. Logan stated that in his case he had seen the ventricular bands approximate on attempted phonation throughout two-thirds of their entire length.

Dr. Curtiss called attention to the fact that cumulative action of alkaloids was impossible in high febrile states.

Dr. Ingalls, in closing the discussion, gave his rules for the administration of strychnine.

Afternoon Session.

Report of Cases of Tubercular Laryngitis Treated in Colorado Springs.—Dr. S. E. Solly, of this city, read a paper with the above title. Forty-five cases showed decided evidence of tubercular laryngeal affection, among a continuous series of 250 cases of phthisis. In order to give sufficient time for results no cases have been taken of phthisis or laryngitis that were seen for the first time less than two years ago.

Among the 250 cases of phthisis there were 45 with tubercular laryngitis, twenty-eight per cent.; 25 with infiltration without ulceration and 20 with both, that is, eight per cent. The average duration of the 25 cases without ulceration, from their first symptoms up to the time of this report or death, was six years, while of 8 of these who got worse it was three years and ten months. Of the 20 cases with ulcers the average duration was three years and two months, while of 15 of them that got worse it was two years.

After taking all the laryngeal cases that deteriorated, the average duration of life was two years and seven months. Forty-eight per cent. of all the laryngeal cases improved. There was sixty-eight per cent. of improvement among the non-ulcerated cases and twenty-five per cent. among the ulcerated cases.

In considering the improvement in the throat alone, in 64.2 per cent. of the whole 45 laryngeal cases there was local permanent arrest, and besides in 5 more cases there was well-marked temporary improvement. Among the non-ulcerated alone the local improvement was sixty-eight per cent. Among the 20 ulcerated cases fifty per cent. healed and remained healed, while 3 additional cases healed temporarily. Of these 20 cases in twenty per cent. the lungs were in the last stage of tuberculosis, fifty per cent. of whom were generally improved, and in seventy-five per cent. there was local arrest of the laryngeal disease. Thirty per cent. were in the second stage of pulmonary tuberculosis, of whom 16.6 per cent. were generally improved, 66.6 per cent. having arrest of throat disease. Fifty per cent. were in the third stage as regards their lungs, and showed twenty per cent. of general improvement, while in thirty per cent. of them there was arrest of the laryngeal complication. The ulceration in thirty per cent. was found in the commissure, of whom 33.3 per cent. improved. Upon the arytenoids in forty-five per cent., with none improved. Upon the false chords in twenty per cent., none improved. Upon the epiglottis in thirty per cent., seventeen per cent. improved, and upon the true chords in fifty per cent., of whom thirty per cent. improved. In the majority the ulceration was not limited to any one of those parts. The author believes these cases would not have shown such good results, even in the Colorado climate, without careful local treatment, though it was shown that similar treatment had been skilfully applied in a low climate and had failed in most cases. As a general principle stimulation is preferred to sedation, while cleanliness is of the

utmost importance, and a variety of drugs and methods are called for and useful in their turn.

Notes of Cases of Tubercular Ulceration of the Larynx Treated by the Krause Method.—Paper by Dr. T. Morris Murray, of Washington, D. C. Statistics of results obtained by this method in Krause's practice were given and cases were reported, including tubercular ulceration occurring on the soft palate, uvula, walls of pharynx, and in the larynx.

Conclusions: Whenever lactic acid can be applied directly to the granulating surface of a tubercular ulcer the pain accompanying such ulcer is promptly relieved, and the ulcer soon heals. These results are obtained whether great debility be present or not. The relief afforded the patient by these applications warrants their use even in cases where there is no hope of prolonging life.

The Use of the Formates in Ulceration of the Pharyngeal and Laryngeal Mucous Membrane.—A paper with this title was presented from Dr. E. L. Shurly, of Detroit. He said that the caustic properties of formic acid had long been well known. He had had the acid prepared in the usual way from formic acid and glycerine, and then combined with the bases of sodium, calcium, ammonium, barium, copper, and iron. He had also prepared the iodoformates of sodium, ammonium, calcium, and iron. All were poisonous to mice in doses of from one-half to two grains when used hypodermatically. If given by the stomach the effects were the same, but more slowly manifested.

To rabbits, five to ten grains of the copper calcium and barium salts proved fatal. All the salts seemed to act as anti-toxines to the growth of pus and to the bacilli in tubercular sputa, and as well to various bacteria. The formates of sodium and ammonium seemed the least poisonous. When given to monkeys a reddened tongue, salivation, and inordinate appetite alone were noticed.

The salts of sodium, ammonium, and iron had been given to patients with lupus, sarcoma, and epithelioma; also in tubercular lesions. A slight stomatitis had occasionally occurred, but no effect on the lung process had been appreciable in the tubercular cases. The only features noted were the same as in the monkeys. The remedy had also been used in spray and by insufflation, being mixed in the latter instance with half its weight of starch. A five to ten per cent. solution of the sodium formate was useful in epithelial, tubercular, and syphilitic ulcerations. The formate of iron seemed serviceable in septic processes. No pain was caused in any of these instances though the copper preparation might occasion a slight stinging.

In the discussion arising upon the three preceding papers Dr. Mackenzie said that we were now in a position to promise our patients a cure in many of the tubercular lesions of the upper respiratory tract.

Dr. Price Brown had seen one case of tubercular infiltration and ulceration in the larynx completely healed. He used the galvano cautery at first, but later curetted, not using lactic acid but rather menthol in albolene (five to ten per cent.).

Dr. Merrick, of Baltimore, had used lactic acid faithfully, but had never seen a case heal under its employment.

Dr. H. H. Curtiss, of New York, thought that the general environment in Colorado had had much to do with the good results reported in Dr. Solly's paper. He had previously reported three cures out of four cases, but two of these had since relapsed. A following out of such cases for five years would lessen the percentage of cures. In his remaining case the left vocal cord was entirely eaten away, but a fleshy shred (probably some fibres of the thyro-arytenoid muscle) had appeared on its site and acted very well as a vibrating medium.

Dr. Delavan alluded to the fact that a case would occasionally heal without any treatment. Other cases were arrested by appropriate topical medication. Krause's and Heryng's plan of curettement with lactic acid had relieved many, and finally good results were promised by Trudeau's modified tuberculin, prepared in a way entirely different from that of Koch. The utopia for tubercular cases would be the proper climate, where the proper treatment could be systematically applied. The phlegmatic disposition of the Germans gave Krause and Heryng better results than we could obtain in this country.

Dr. Ingalls had tried sodium formate, but without any special results. Two cases had received much benefit from the application of terchloride of iodine (gr. j. to ijss. to water ℥ j.); when it came in contact with purulent matter it was decomposed and nascent iodine liberated.

In closing the discussion Dr. Solly said that the good effects of environment, in Colorado, were often nullified by the patient's homesickness and anxiety when away from friends and business. We should be thorough in our curetting of the diseased surface and follow out a "bed-rock" plan of treatment. One advantage Colorado practitioners had was that they saw their patients more often, and were more intimately acquainted with their mode of living than was the case with the patients of their Eastern confrères.

SECTION ON GYNECOLOGY AND ABDOMINAL SURGERY.

Second Day, Wednesday, September 6th—Morning Session.

The Technique of Total Extirpation of the Fibromatous Uterus, was the title of the first paper, read by Dr. George M. Edebohls, of New York. He enumerated the steps of the operation as follows: Place the patient in the lithotomy position. Thoroughly disinfect the vagina. Disinfect the uterine cavity, as far as possible in each individual case, by means of superficial curetting and irrigation with 1 to 2,000 sublimate solution. Pack the uterine cavity moderately full of sublimate gauze, 1 to 100. Pack the vagina tightly with sublimate gauze 1 to 1,000. Make no vaginal incisions; do none of the cutting from below. Now place the patient in the Trendelenburg posture. Open the abdomen above the pubis by an incision just large enough to permit of delivery of the entire tumor. Given a tumor weighing not above four kilogrammes, with healthy tubes and ovaries, proceed as follows: Eventrate the tumor. Circumscribe two peritoneal flaps by two transverse incisions of the peritoneum, one on the anterior, the other on the posterior surface of the tumor mass, each incision extending from one broad ligament across to the other. These peritoneal flaps should be large enough to easily cover the defect in the pelvic floor left after removal of the uterus. Strip the peritoneal flaps from the surface of the uterus, carrying the bladder and ureters forward, out of harm's way, with the anterior flap. Tie the uterine arteries on either side by a subperitoneal mass ligature of catgut, carried well down to, but not into, the vagina. The distention of the vagina by the gauze packing makes this an easy matter. Tie off the broad ligaments, outside of the tubes and ovaries, by two further catgut ligatures on either side. Cut out the entire uterus, tubes and ovaries, in one piece, between the ligatures. Cut short the six ligatures. Unite the peritoneal flaps by a transverse, running Lembert suture of catgut, extending from the stump of one infundibulo-pelvic ligament to that of the other, carefully applied so as to securely close the peritoneal cavity and turn all ligatures down into the vagina. Close the abdominal wound. Again place the patient in the lithotomy position. Remove the gauze packing from the vagina and apply a loose dressing of gauze in such a manner as to drain the supra-vaginal subperitoneal space. If the ovaries or tubes present evidences or suspicion of containing infectious material, tie off and remove them the first thing after opening the abdomen. If the tumor extend above the umbilicus, weighing more than about four kilogrammes, pass a rubber ligature around the cervical part, after stripping back the peritoneal flaps,

and amputate the bulk of the tumor. Cauterize the cervical canal with the Pacquelin or a tablet of corrosive sublimate, and remove the cervix in the manner described above. If multiple fibromata, or intra-ligamentary fibromata, fill the pelvis, make room by enucleating the fibromata most in the way, and proceed as above.

The technique advocated is believed to possess the following advantages: The danger of infection from the uterus or vagina is entirely avoided, or at least minimized. The uterine arteries are secured with ease and certainty. The operation is practically bloodless. The closure of the peritoneum is as perfect as it can be made, and no foreign body is left in its cavity. The after-treatment required is practically nil.

Discussion of the paper was reserved, to be taken up together with that of a similar subject which next followed.

Hysterectomy: Indications and Technique, was the title of a paper read by Dr. J. M. Baldy, of Philadelphia. He said it is not proposed to discuss in this paper the etiology or symptomatology of the various conditions for which this operation is performed. It is not always safe, in forming conclusions, to draw our inspiration from a promiscuous collection of statistics, therefore, whatever deductions are drawn will be entirely from the author's personal experience, which has reached the number of seventy-seven hysterectomies.

The indications, as taught by this experience, are absolute and relative. They are: 1, malignant degenerations; 2, fibroid tumors; 3, pelvic inflammations; 4, prolapse; 5, inversion.

The indications in malignancy are absolute, both as to the advisability of operation and as to the complete removal of the uterus. However small the number of cases cured may be, yet it is an undisputed fact that a certain proportion regain permanent good health. Should only one or two in a hundred be so fortunate, yet would the operation be justified in view of the absolutely certain end of all without it. The operation is comparatively safe. Twenty-five operations have been performed by the writer for primary cancer or sarcoma of the uterus, and of this number three have died from the operation; all three deaths were due to preventable cause, and with added experience and a more perfect technique would not be likely to occur again.

The indications for surgical treatment of fibroid tumor are relative. Surgical treatment having been once decided upon, hysterectomy is the proper procedure. Ovariotomy is excluded for the reason that it equally renders the patient sterile; it allows the tumor to remain *in situ*, with the added chance of its not producing a cure; it often leaves a uterus diseased in its cavity as well as its walls; it is as difficult as hysterectomy often; and at times is impossible. Hysterectomy, as the operation of choice, depends upon its mortality. Forty-one fibroid uteri were removed by this means, with four deaths. Three of these deaths were from preventable causes, or accidents which would not be likely to occur again.

The indications for pelvic inflammation are relative. Four such operations have been successfully performed: two subsequent to a primary ovariotomy; two primarily. Patients in whom the endometrium is badly diseased, the uterine walls infiltrated, especially with pus corpuscles, and the whole uterus enlarged, are proper subjects for their treatment.

The indications for uterine prolapse are relative, when the ordinary procedures have failed, when the patient is near, or past, the menopause, and when there is the slightest suspicion of malignancy. The operation should be performed with catgut ligatures, the stump stitched into the vaginal opening, and subsequent plastic operations performed upon the anterior and posterior vaginal walls. The operation has been performed six times, always with success.

A chronic inverted uterus should be removed wherever a short trial at taxis and elastic pressure has failed. The operation has been performed once successfully.

The methods of performing hysterectomy are abdominal, vaginal, and the combined method. The combined method is superfluous, and more dangerous than either of the other two alone.

Abdominal hysterectomy is performed by: 1, supravaginal amputation; *a*, treatment of the stump by the extra peritoneal method; *b*, dropping the stump; 2, extirpation.

Vaginal hysterectomy is performed by: 1, clamp operation; *a*, single clamps; *b*, multiple clamps; 2, ligature operation.

All cases of prolapse and inversion, all cases of malignancy sufficiently small, and very small fibroid tumors, are proper subjects for vaginal operation.

Dr. H. J. Boldt, of New York, opened the discussion upon these two papers. He stated that reports that do not make a separate class of broad ligament fibroids are not complete. Reports in which the operator varies his method are not so instructive as reports from different men, each the exponent of a particular method. Dr. Edebohls differs from Martin in one important point, in that he precedes hysterectomy by a curetting. In fibroids that are low and split the broad ligaments, we have a class that is not amenable to either of the two procedures advanced.

Dr. Carsons, of Detroit, thought an ideal operation not always practicable, and that in the interest of the patient we must occasionally use clamps and the extra-peritoneal method. He liked, after disinfecting the vagina, to cut through the mucous membrane as a preliminary step to abdominal hysterectomy.

Dr. Noble, of Philadelphia, thought the supra vaginal amputation preferable to total extirpation, because a safe method—safer, since it is a short method. He had used the bladder to cover over the cervix with good result. In seventeen cases he had removed the ovaries for small fibromata, and with one exception, where the tumor was just large enough to act as a ball-valve in the pelvis, had attained good results.

Dr. Currier considered the introduction of gauze from above as good as through the vagina. Otherwise he approved Dr. Edebohls's method. Dr. Noble's statement that the two broad ligaments that remained constituted stumps, was not correct. The Hegar operation is the best practicable in some cases of fibroids.

Dr. Marcy said he entered upon the discussion without having heard the paper, and thus was in the position of Sydney Smith, who declared he preferred criticising a book before reading it, as thus he entered upon his task entirely without prejudice. The double-lateral continuous suture is preferable to ligatures. The operation best for the life of the patient should not be spoken of as opposed to the ideal operation. The ideal operation is the life of the patient, in that it meets all the conditions that threaten.

Dr. Mcdonald would not leave any thick stump that might slough from ligature of the uterine artery. But a normal cervix needs only disinfection of its canal to render its preservation innocuous.

Dr. McMurtry, calling Dr. Maury to the chair, said that three years ago there would have been raised an objection to considering abdominal hysterectomy for fibromata a legitimate operation. Such a tumor was then spoken of as a benign growth that would disappear at the menopause. Total extirpation was after the German school of Schroeder, Martin, and their followers. We are educated in different schools, and each excels in his own method. We cannot determine beforehand the precise operation. Removal of appendages is uncertain, but it is a grand resort when impracticable to do the severe operation of hysterectomy. For, in his mind, abdominal hysterectomy is the most difficult and masterful operation in all surgery, when consideration is taken of the complications that are likely to be met.

Dr. Margaret Crosedale, of Philadelphia, related a case of fibroid, size of an orange, in which removal of appendages failed to check hemorrhage. In a second simi

lar case she had subsequently to remove uterus per vaginam to effect a cure.

Dr. Johnson had, in quite an extensive series, failed to check hemorrhage by the slighter operation, in but one case.

Dr. T. Johnson Alloways, of Montreal, also had many grievous failures to check hemorrhage by removal of the adnexa to record. He considered it always incumbent upon the operator to dilate the uterus in search of polypus as the possible source of tumor and hemorrhage, before subjecting one's patient to the more serious operation.

Dr. Edebohls, in closing, insisted that cutting through the mucous membrane from below was unnecessary, and in case, after abdominal incision and exploration hysterectomy should be abandoned, it would prove an unfortunate beginning. He claimed for his operation four original procedures — the unvariable curetting of the uterus, the hard packing of vagina, the reflecting of anterior flap of peritoneum, and with it bladder and ureters, out of the field of operation, and the closing of peritoneum below across the pelvis with the continuous Lembert suture. The instruments needed were few and simple.

Dr. Baldy, in closing, objected to being considered merely as a partisan; for, as he had employed the methods advocated by his opponents an equal number of times with them, he claimed a position to fairly judge between supra-vaginal and total hysterectomy. The shortening of the vagina that follows the latter method is an objection that we must not disregard. Dr. Edebohls confessedly takes a half-hour before he is ready for his abdominal incision. In his own last case he had removed the tumor in ten minutes, and there remained only to close the wound. The three great things to avoid were sepsis, tedious operation, and hemorrhage. Sepsis was less liable through the cervical canal than through the vagina, hemorrhage was no more likely to follow from the portion of cervix that remained, than after a trachelorrhaphy; therefore, he claimed for supravaginal hysterectomy advantage in every respect over pan-hysterectomy. As for the extra-peritoneal treatment of the stump by attaching it in the abdominal wound, it commended itself for its safety to unskilled operators, but we have heard the last of it from the specialist.

A Plea for the Early Diagnosis and Prompt Electrical Treatment of Fibroid Growths of the Uterus, was next read by Dr. G. Betton Massey, of Philadelphia, who said: The questions briefly considered in this paper are: the nature and symptoms of the early manifestations of uterine fibrosis and myomatous new-growths; the duties of the profession in making a prompt diagnosis and instituting early treatment for the condition; and a consideration of the value of the Apostoli methods in these cases results in the following conclusions: 1. The early signs of uterine fibrosis are quite similar to those of a number of more common disorders, and are consequently mistaken for them in many instances. Whenever metritis, displacements, or persistent sensations of pain and weight are found, the physician should bear in mind the possibility of the cause being an incipient fibroid development, and if found to be so, he should place the patient at once under treatment. 2. The most recent views of the etiology of fibrosis indicate that the mode of action of electricity is most likely by a stimulation of the trophic and sorbefacient functions of the uterus, rather than by an electrolytic destruction of the growth. 3. The expectant policy in dealing with fibroids is too prevalent, resulting in many cases losing the decided advantage to be derived from early treatment. 4. The early diagnosis of fibroid growths has the advantage of placing all cases within the list of those that are amenable to electrical treatment, while delay permits of some becoming unsuitable for it. 5. All forms of fibrosis and fibroid neoplasms of the uterus are suitable for electrical treatment, except those that have undergone cystic changes, or that are accompanied by purulent accumulations in the uterine adnexa.

The meeting then adjourned.

Afternoon Session.

The Results of Vaginal Hysterectomy, the first paper of the afternoon session, was read by Dr. Andrew J. McCosh, of New York, who prefaced his report with a few general remarks. Vaginal hysterectomy has proved superior to high amputation, but is not to be undertaken if bladder or broad ligaments be invaded by malignant growth. If uterus is more than twice its normal size, abdominal section is to be preferred. The appendages need not be removed unless they are diseased or prolapse. Iodoform gauze is to be left in vagina for some days. It is necessary to employ the sacral exposure of the uterus only in those cases that are best left alone.

The object of the paper is to record the personal results of the author. No new methods or instruments are proposed. All the cases of vaginal hysterectomy operated on by the author are reported and classed as (1) for cancer, (2) for prolapse.

First, for cancer. Ligatures are preferred, but clamps are used without hesitation, provided they can be applied with greater ease or safety. Silk has been employed for ligatures. All specimens were examined microscopically.

Thirteen operations are reported. No deaths. There are in perfect health, without sign of return, at end of five years, 1 patient; four years, 1 patient; two years, 1 patient; one and one-half year, 1 patient; one year, 2 patients; four months, 2 patients. There have died from return of the disease, at the end of thirty-three months, 1 patient; seven months, 1 patient. There are still alive, but with return of the cancer at the end of three years, 1 patient; one year, 1 patient. Disappeared from observation, 1 patient.

Second, for prolapsus uteri. For ordinary cases of prolapse hysterectomy is unjustifiable. Milder measures are sufficient. In certain cases, however, of complete prolapse of a very large uterus and of an enormously hypertrophied vagina, the ordinary plastic operations (perineorrhaphy and colporrhaphy) are apt to be failures as a means of permanent support. In such cases hysterectomy is a justifiable operation.

Report of five cases (four of the author's), no deaths: Complete success, 1 case; partial success, 2 cases; failure, 2 cases.

It is doubtful if we can expect perfectly satisfactory results from this operation, even when followed by a perineorrhaphy. The operation is rather tedious and bloody.

Cavernous Angioma of the Uterus Removed per Hysterectomiam Vaginalis, with Remarks upon the Method of Doing Vaginal Hysterectomy.—Dr. H. J. Boldt followed with a paper with this title. After exhibition of the specimen and an account of the case, the author proceeded. No fixed rule can be laid down, each case must be managed according to the circumstances presenting themselves at the time. We will, however, take an ordinary case, such as the one from whom the uterus presented was removed. It is immaterial whether it be malignant or non-malignant disease for which the operation is done, as far as the one feature is concerned, viz.: the closing of the wound completely and to have the broad ligament stumps entirely extra peritoneal. The portio having been grasped by vulsella and the uterus pulled down as much as possible, a transverse incision is made anteriorly and the bladder stripped off the cervix; if it cannot be completely done yet, only so much is separated as is convenient. The same course is pursued posteriorly, and the cul-de-sac of Douglas is opened. The peritoneum is now attached to the vaginal mucosa by a continuous catgut suture. The base of the parametria are next ligated and cut on either side. Should the bladder not have already been entirely separated, it will be found to be easily accomplished after severance of the base of the parametria. The broad ligaments are now

ligated in sections and cut as we proceed, taking care that the needle enters the vaginal mucosa, and after taking in its grasp as much of the broad ligament as is desired, it emerges again in the vaginal mucosa. The index-finger of either hand is used as a guide, by way of the posterior opening. After tying the ligature, the ligated portion of the broad ligament is cut. The adnexa are brought down and ligated off if possible in the same manner. It it obvious that by following this technique of introducing sutures, that our stumps are practically already secured in the vagina. The terminal ends of the stumps are now grasped with bullet forceps, and an assistant makes traction sufficient to bring them completely into the vagina, when another suture is passed on the same principle as the previous ones, enveloping all the stumps. This done on either side, the centre gap can now be closed completely, after removing the sponge or gauze tampon from the pelvic cavity, if one has been inserted to prevent the intestines from prolapsing during operation.

Full-curved sharp needles of suitable size are used, and nothing but catgut for ligatures. Silk delays convalescence too much, and it cannot be made more aseptic nor tied more securely than animal ligature. The needle-holder is also preferable without catch or spring. There is no necessity for drainage in ordinary cases, so that the practice of putting a strip of gauze into the pelvic cavity for this purpose in every instance, had better be abandoned. It is only desirable when extensive perimetrial adhesions are present. In malignant disease the operation must be done as far away as possible from the diseased structure, and sufficient vagina must also be resected if the portio is the seat of the neoplasm. Clamps should never be used if ligatures are applicable.

The operation should be done with the patient in the lithotomy position, and not in the side position.

Vaginal Hysterectomy.—The third paper upon the subject was read by Dr. E. E. Montgomery, of Philadelphia. He said: This is now an accepted operation. Under improved methods the greatly reduced mortality, with the increased immunity against relapse, renders it the effective operation in malignant disease when confined to the uterus. In uterine fibroids of small size, whether involving the cavity of the uterus or its walls, it is preferable to dilatation and enucleation for their removal. It may be done in some cases of prolapsus of the uterus, particularly when accompanied with extensive ulceration of the cervix. Its performance for pelvic inflammations demanding removal of the ovaries and tubes, may be questioned. The use of the clamps greatly expedites the operation, and saves the patient from the effects of shock resulting from a prolonged operation and long-continued anæsthesia. In 21 cases in which the writer has performed vaginal hysterectomy, 16 were done for undoubted malignant disease, in one of which there was epithelioma of the cervix and a number of fibroids in the body of the uterus; 3 for fibroids, and 2 in which the diagnosis was doubtful. In 21 cases there was 1 death from tetanus, on the fourteenth day.

At the request of the President, Dr. Kelly, of Baltimore, opened the discussion upon the three papers. He said that we are now crystallized, except in minor details, in regard to the treatment of cancer of the uterus. Prophylaxis consists in inspection of every woman three months after confinement, and then every year until she is past the menopause. Lacerations of the cervix should be repaired. Malignant growth is frequently grafted upon these hard, infiltrated cervices. We are sometimes surprised at unhoped-for results in desperate cases.

Open vagina, in the multiparæ, back to the rectum if necessary. Pass silk thread through the lips of the cervix; it acts then to close the uterine cavity, and also as a tractor. Free one side of uterus entirely first, in order that the fundus may be brought out, and the other side more deeply diseased, more widely removed. The mortality ought to be very nearly *nil*. With him, for the past year and a half it had been quite so.

Dr. Noble thought vaginal hysterectomy not applicable in prolapse, except in small uterus with prolapse of Douglas's pouch to level of anus. High amputation is preferable in some cases; in others, ventral fixation. Later perineorrhaphy is needed.

Dr. Edebohls did not consider hysterectomy indicated for prolapsus, except when new-growth is expected, or there is great cervical hypertrophy. He was accustomed to combine neutral fixation with plastic operations at one sitting, as we lose the full effect of one operation while waiting for the other.

Dr. Currier thought the progress in treatment of cancer to a more radical ground, comparable to the history of treatment of ectopic gestation. We should practise catheterization of the ureters previous to hysterectomy, in order surely to avoid them. Recurrence should be treated by cautery after method of Dr. Byrne, of Brooklyn.

Dr. Baldy lost two of his three cases treated by clamps through overlapping of the distal ends, and so had no liking for that method. In skilled hands hysterectomy is as safe as hysterorrhaphy, and if the broad ligaments are attached so as to raise the vault of the vagina, that method will prove more successful in the treatment of prolapse.

Dr. McCosh thinks silk is gaining ground from catgut in abdominal use. He had not found it necessary to perform the preliminary curetting in cancer at a previous sitting.

Dr. Montgomery had performed all his clamp operations in from ten to thirty minutes, and thought they could safely be removed in twelve hours, though he waited twenty-four.

Present Status of Our Knowledge of the Pathology of Pelvic Inflammation, with Special Reference to the Anatomy and Treatment of Pelvic Abscess.—This was the last paper of the afternoon, by Dr. R. B. Maury, of Memphis, Tenn. He said: The term "pelvic abscess" applied to any collection of pus in the pelvis, no matter what its anatomical relations. Views of pelvic inflammation ten years ago, compared with accepted doctrines of the present time: Pelvic cellulitis known to be an acute inflammation, occurring as one of the features of a puerperal septicæmia. It also occurs as a result of the infection of surgical injuries upon the uterus or vagina. To the extent of producing appreciable exudations, it is of infrequent occurrence even in the puerperal inflammations. Death following septic infection of surgical operations is usually due to peritonitis; cellulitis is seldom found. The dissecting-room proves that pelvic cellulitis to a *minor* extent frequently occurs in association with a *major* peritonitis. In such cases the cellulitis would be incapable of recognition at the bedside. Chronic pelvic cellulitis as a distinct pathological condition believed to be a misnomer, and is of doubtful existence. Clinically, it is impossible of recognition. Pelvic peritonitis associated with diseased uterine appendages is regarded to-day just as it was taught thirty years ago by Bernutz, the keystone of pelvic pathology in women. The collections of pus, here to be considered, are those which follow inflammation of the pelvic cellular tissue, and those which result from salpingitis, ovaritis, and pelvic peritonitis. Abscesses of the cellular tissue are rare. Broad ligament abscesses are very infrequent. Lack of scientific accuracy in the anatomical reports of them. The overwhelming majority of pelvic abscesses are intra-peritoneal. As long as pelvic cellulitis dominated pelvic pathology all the surgical methods for the evacuation of pus were based upon operations through the vagina, or through the anterior abdominal wall. Such methods are applicable to a very small number of cases.

Methods of treatment of pelvic abscesses: 1. Of abscesses extra-peritoneal. 2. Of intra-peritoneal abscesses. Abdominal section the natural method of approaching intra-peritoneal abscesses. It offers advantages which no other possesses. It should be essayed in cases when the exact nature of the abscess is in doubt.

THIRD DAY, THURSDAY, SEPTEMBER 7TH — MORNING SESSION.

Relations of Urinary Conditions to Results of Operative Surgery, was the first paper of the day, by DR. CHARLES P. NOBLE, of Philadelphia. A study of five hundred cases shows that ten per cent. have albuminuria, and yet the prognosis, especially in our gynecological cases, is not necessarily bad. Neither albumin nor tube-casts are always significant of serious disease. Large abdominal tumors are particularly prone to give albumin in the urine, and often casts. These disappear after operation. Examination of urine should include the amount passed in the twenty-four hours, and the quantity of urea. As a rule, the tumor cases showing degenerative changes in the urine do well after operation, but the salpingitis cases badly. The average amount per diem passed, for the first four days after cœliotomy, is about fifteen ounces. The comparative irritant properties upon the kidneys of chloroform or ether is uncertain.

DR. LAPTHORN SMITH, of Montreal, had seen albuminuria relieved by the withdrawal of a pail of serum from the abdomen in malignant disease, just as we know the emptying of the gravid uterus relieves the albuminuria of pregnancy. Prolonged etherization will cause temporary albuminuria in the healthy, whereas anæsthesia may be accomplished for the same period by chloroform without that result.

DR. JOHNSON was relieved by the record of the small amounts of urine usually passed after cœliotomy. He had frequently been alarmed at the reports of nurses of the small quantity that was being passed, and would inquire when the condition might be considered suggestive of suppression. He had learned by experience that it is important to have examinations of urine made earlier than of the night and morning preceding operation.

DR. BOISE, of Grand Rapids, maintained that when the urine is to be increased it should not be by drugs acting upon the already irritated kidneys, but by the injection of water in the bowels.

DR. CARSTON, in spite of the substitution of chloroform for ether in his practice during the past year, had lost two cases from uræmia. The disturbance is primarily of the renal plexus of nerves, either from pressure or septicæmia. He relieves the kidneys by inducing diaphoresis, and gives water by both mouth and rectum. Doubts if the anæsthetic has much to do with the condition. Strychnine in as high doses as a quarter-grain and atropine do most in the way of drugs.

DR. STONE believed that Bright's disease exists in some cases that cannot be determined by the urine. The cardiac and arterial conditions suggestive of a general fibrosis may be our only hint.

DR. CUSHING, of Boston, was of the opinion that ether is often blamed when the condition is one of septicæmia. These great emunctories of the system are first overcome by the sepsis that they are endeavoring to throw off, and the suppression is but the first symptom of a general toxæmia. Bacteria that will ordinarily be flushed out, through a temporary suppression, gain a foothold in the kidney; or a cystitis, caused by the previous catheterization, or already existing, seizes opportunity to pass up the ureters and attack the kidneys. An unwitting ligation or laceration of the ureters is a cause not entirely out of the range of possibility.

DR. NOBLE had been brought up to use chloroform where trouble from the kidneys was apprehended, but doubted now its superiority to ether in that respect. The prognosis of surgical kidney is just as bad in the countries where chloroform is used as in those employing ether. At present his inclination is to use ether in all cases. The shock and exposure have more to do with the suppression than the anæsthetic. The diagnosis will lie, not between normally small amount of urine and suppression, but between suppression and septicæmia.

Drainage of Ovarian Cysts where the Adhesions are Such that it is Impossible to Remove the Sac, was the title of a paper next read by DR. A. VAN DER VEER, of Albany. We may be surprised at the number of adhesions that exist even when the history of pain, and other symptoms indicating a local peritonitis, is wanting. One of the causes of such adhesive inflammations that we are to guard against inflicting upon the patient, is too frequent or too prolonged examination. Our zeal to rid the patient entirely of her cyst may lead us to extend an operation at the cost of life. In some cases it is better to abbreviate the operation, and drain some portion of the cyst wall. Adhesions in the pelvis may be broken with very little subsequent shock, while those to the colon and abdominal viscera are more serious to invade. Drainage is best effected by glass tubes or gauze. Six cases thus treated, that could not have sustained the complete removal of the sac, made a good recovery, with one exception. Here the patient passed from under treatment before the abdominal sinus closed, and infection of its tract caused death from peritonitis.

DR. CURRIER said that a false feeling of security is often acquired from a long series of successes, that the operator is only awakened from by an unexpected death. We will not clear up every area of induration at the expense of the patient. It is true some patients are septic before operation, and it requires only the shock of the operation to turn the scales against them.

DR. NOBLE believed that it is sometimes wise to stop in an operation. Oldshausen and Schroeder teach to remove everything. Especially in cases of malignant growth and papillomatous cyst, it is frequently wise to desist, using perhaps a quantity of gauze for drainage. In non-malignant cases, where the adhesions are limited to the pelvis, better go ahead. It is the adhesions in the abdomen that are dangerous.

DR. SMITH said that the cautery and iron solutions should not be used in the abdomen as styptics. In one case, at a second operation, he had found very dense adhesions over a point where the cautery had been used.

DR. VAN DER VEER noted as an exception that adhesions making knuckles in the intestine should always be broken, and advocated the discarding solutions of iron and the thermo-cautery as styptics in the abdomen.

The After-treatment of Cœliotomy Cases, with Special Reference to Shock and Sepsis.—Paper by DR. EUGENE BOISE, of Grand Rapids, Mich. He said there are three post-operative conditions which call for prompt intelligent action: secondary hemorrhage, shock, and septic peritonitis. Shock is some form of paresis of the sympathetic nervous system. I believe that it is primarily hyper-irritation of the entire sympathetic system. The primary condition in shock is severe stimulation of the entire sympathetic system, with consequent cardiac and arterial spasm. The second stage of shock may be a so-called paresis by reason of the exhaustion of the heart. The remedies, therefore, would be, for the first stage, free hypodermics of codeine, nitrite of amyl, and nitro glycerine, with copious injections of hot water into the colon. For the second stage, strychnia, digitalis, and cardiac stimulants, with, if necessary, intra venous transfusion of hot saline solution.

All operators have an instinctive feeling that prevention of sepsis prevents peritonitis, and, therefore, the efforts are directed to prevent the entrance of septic material into the cavity; or, if the material removed is of septic nature, to cleanse the cavity as thoroughly as possible and to remove the fluid, which would otherwise invite infection. The two post-operative measures relied on for this purpose are drainage and free catharsis. Drainage may be accomplished by tube or gauze, and if used must be thorough.

In the production of catharsis several factors are to be kept in mind. First, after every cœliotomy there is a flow of serum from the blood-vessels into the peritoneal cavity, thus depleting the vessels.

Second, during the first few hours after a cœliotomy of any considerable severity there is more or less paroxysmal abdominal pain, sometimes very severe. This is

caused by irregular and spasmodic peristalsis, the muscular coat of the intestines contracting unequally, and, it may be, tonically obstructing the bowels.

Third, by reason of the withholding of fluids, the intra-peritoneal serous effusion, and, it may be, profuse perspiration, the blood-vessels of the intestines are greatly depleted. For the easy production of catharsis the current should have ceased to flow from the blood-vessels toward the peritoneal cavity.

The spasmodic contraction of the intestines should have been overcome, and the blood-vessels should have been replenished. The serous effusion will cease after a few hours. The spasmodic contraction of the intestinal muscles should be overcome by a hypodermic injection of a free dose of codeine, and the blood-vessels should be filled by means of hot water thrown into the colon. Then catharsis may be produced with comparative ease.

In the discussion that followed Dr. Cushing suggested as an addition in the treatment of shock the subcutaneous injection of hot water. Codeine is to be given at once, if at all. It is difficult to say whether intestinal obstruction precedes sepsis, or *vice versa*.

Dr. Noble emphasized the prophylactic treatment of shock. Patient is to be put in best possible physical condition for the operation. The room is to be kept at a temperature of 75° to 85° F. The body, as far as possible, should be covered with blankets. Wet towels through evaporation, even if wrung out of hot solution, refrigerate the patient, and should give place to dry ones, which can be made equally aseptic.

Strychnine in dose of gr. $\frac{1}{15}$ is very valuable, and its manifest value in shock, in so far as exhibited in the early stages, militates against the theory of over-stimulation of the sympathetic system. He is accustomed to giving one eighth grain of morphine when there is any pain or shock.

Dr. Robert T. Morris said, that it had been shown that water produces changes upon the surface of the peritoneum, and through slight adhesions and roughenings lessens its absorptive powers, and hence renders a development of sepsis more probable. Specimens of animal tissue cannot be preserved in water, but undergo change very slowly in normal saline solution. A normal saline solution is the only fluid that should be used in the abdominal cavity.

After a brief review of the discussion by Dr. Boise, an adjournment for the noon recess was taken.

Afternoon Session.

This session was not upon the calendar, which designed combining this section with those of general surgery and general medicine, for the discussion of the anæsthetics, but was held by the unanimous desire of its members in view of the number of interesting papers that remained still to be read.

An Inquiry into the Etiology of Mental Disturbances Following Operations upon the Pelvic Organs in Women, was the title of a paper read by Dr. George H. Rohé, of Catonsville, Md. The author claims that an analysis of the evidence available shows that a large proportion, perhaps the majority, of cases of mental disturbance following operations upon the pelvic organs, is due to the same causes that produce insanity subsequent to surgical operations generally. These causes are in some cases shock; in others, sepsis; in others, intoxication from drugs or antiseptics used during or after the operation.

In a certain proportion of cases of insanity following operations upon the pelvic organs in women, the mental disturbance is due to the artificial induction of the menopause. In a minority of cases, the mental disturbance is probably due to the shock of the operation in a person hereditarily disposed to insanity.

Dr. Currier related a case of melancholia following the Hegar operation, and one following plastic operations upon the cervix and perineum, performed two months after the subject had endured a four-days protracted confinement.

Dr. Joseph Price, of Philadelphia, spoke of the frequency with which we may observe mental disturbance, associated with low grades of septic infection, in the subjects of fibroids and of ectopic pregnancy. Out of the eighty-six cases of ectopic gestation that had come to him for operation, not one was right mentally. No one living or dead has contributed more to this subject than has Dr. Rohé; criticisms that the secular press has seen fit to lay upon him notwithstanding. Five, ten per cent., perhaps more, of the women in asylums can be taken out. Displacements corrected rectify mental condition. Bad midwifery, too much surgery, are causes of producing mental derangements. Hysterectomy often produces a peculiar change of mental condition and disposition. The subjects are not insane, frequently they could be more comfortably disposed of if they were insane. He is often reminded of the first hysterectomy case—that of Keith, of Edinburgh. Six weeks later she came back to the surgeon, and complained of a potato having been served to her, while she was in the hospital, with its jacket on. They are not insane, but——.

Dr. Rohé, in closing, said that profound anæmia is one of the causes of insanity. Sepsis that existed before the operation is in some cases the patent factor of the insanity that has followed.

If the blood and the general constitution were all right, not one case of operation in five thousand would be followed by insanity.

Extra-peritoneal Treatment of Stump in Abdominal Hysterectomy, was the title of the next paper, by Dr. Joseph Price, of Philadelphia. The picture that is frequently drawn of this method, of a large mass of flesh, foul in odor, sloughing in the abdominal wound, leaving after it an abdominal sinus, is far from the truth. In truth the stump is usually nothing but a small dry button that withers and drops off in four or five days. The opprobrium attached to the *sourd-nœud* method belongs by right to the operators with whom the accidents enumerated happen. As for those who make such an ado about the difficulty of finding a place to apply the constriction, he could think of no other suggestion than that the *nœud* be applied to the operator's neck. The scientific method can be no other than that which proves most successful. From this standpoint a series of one hundred and thirteen cases treated by him by the extra-peritoneal method, proves that the operation is highly scientific.

Leopold, after losing five out of twenty-two cases of intra peritoneal treatment of the stump, recommended that the extra peritoneal be resorted to where the patient is unable to withstand the shock of a long operation. If the wire cannot be applied, better remove the whole uterus. The total extirpation method is a good one, but not so safe as the fixation of the stump.

One Hundred Operations for Severe Structural Disease of Abdominal and Pelvic Organs of Women, was the title of a paper by Dr. I. S. Stone, of Washington. A detailed account was given of the diagnoses, treatments, and results of a series of cases that were operated upon only after an examination, and a unanimous approval by the whole staff of the hospital. The series embraced seventeen cases of pelvic abscess, twenty-one cases of tubo-ovarian abscess, and eleven of myoma uteri, and the total mortality was fifteen per cent.

After the reading of the paper the section adjourned until the following morning.

Fourth Day, Friday, September 8th — Morning Session.

Discussion upon the papers of Drs. Price and Stone of the preceding day opened the order of the last session.

Dr. T. Johnson Alloway considered that, when one is not likely to meet in his practice more than a half-dozen cases demanding hysterectomy from his hands, it is mad-

ness for him to attempt the intra peritoneal method. Out of seventy cases of fibromata that had presented themselves to him, he had judged but four or five of them to need operation. He could present fifteen of that number in whom the symptoms had all disappeared, and who were as rosy-cheeked as one could wish to see, through treatment by the Apostoli method. His predecessors' cases, operated upon by the intra-peritoneal method, had nearly all died, and so he had chosen fixation of the stump when he was forced to operate. The stump may be kept perfectly dry and aseptic until it falls off, by keeping it imbedded in dry boracic acid. He has seen patient bleed to death from the total extirpation of the uterus. Martin's operation has a mortality of twenty-five or thirty per cent., and in the hands of the smaller operators, at least, the extra-peritoneal method is preferable.

Dr. Stone criticised Dr. Price as assuming that we had reached perfection in our method of hysterectomy. Tait had proved that by reflecting the peritoneum from the lower segment of the uterus and the broad ligaments, and thus lessening tension of the stump, the mortality was lowered. But at that point Baer's method is three-quarters done. In skilled hands the latter method can be completed as rapidly as the former is being done.

Deductions from my First One Hundred and Ten Laparotomies for Appendicitis, with Report of Experimental Investigations, was next read by Dr. J. B. Murphy, of Chicago. He said that the appendix is usually situated a little below the mid-point from umbilicus to anterior superior spine of the ilium, though it may be found near the kidney to the left of the uterus, or even near the spleen. By far the greater number of cases of retention appendicitis are from impaction of fecal concretion. Thus in forty cases, thirty-eight fecal concretions were found in the appendix, and only two foreign bodies, such as grape-seeds.

Seventy per cent. of autopsies from appendicitis showed perforation of the appendix, and yet suppurative peritonitis may occur without perforation. Local gangrene is caused by stoppage, infection of the walls, or torsion. A perforation is usually followed by local adhesions, that are afterward broken by accumulations of pus. An extra-peritoneal abscess is not formed as formerly supposed, but has for its outer wall the parietal peritoneum, and for its inner the adhesions that separate it from the general peritoneal cavity. Sudden collapse may occur immediately after the bursting of an abscess into the general peritoneal cavity; it is then from rapid absorption by the broad surface of peritoneum of ptomaïnes. Usually collapse happens only several days after the rupture occurred, the rupture at the time giving no signs. For it is impossible to regard the amount of pus we sometimes find in the abdomen, in an operation following collapse, as the accumulation of less than several days.

There may be a general septic peritonitis, with a pulse of 90, and temperature of 99° F. 1. Sudden attack of pain; 2, nausea or vomiting; 3, localized tenderness over appendix; 4, elevation of temperature. All four of these signs are needed to diagnose an appendicitis, and with them the diagnosis has never proved false.

The estimated mortality of all cases of appendicitis is twenty-seven to thirty per cent. The mortality, in his series of one hundred and seventeen cases that were operated upon, was between nine and ten per cent. The intrinsic peril of operation is practically *nil*.

Incision is to be made over the McBurney, or Kraft, point. The sides of the cavity are to be packed with gauze that remains five to fifteen days. Never irrigate, but use dry sponging. Manipulation of peritoneum, roughening its endothelium, increases its liability to suppuration, and besides the fluid is likely to carry pus into healthy recesses as well as out of the wound.

When removal of the appendix necessitates breaking the wall of adhesions it is not undertaken, but the patient is instructed to summon the surgeon at the first symptom of the return, that is almost inevitable. At that time the appendix is removed before pus has had time to form. Thus from eight cases in which he could not remove the appendix at the first operation, in six he has secured it at a second.

The reading of this paper was followed by another one upon the same topic by Dr. Robert T. Morris, of New York.

Infectious Appendicitis.—Dr. Morris said that within the outer serous envelope that formed an indistensible tube, was an inner tube made up of mucosa, adenoid, and muscular tissue. Thus the structure is precisely the same as of intestine, but the calibre is very small. Appendicitis is an infectious, exudative inflammation from displacement of the guarding epithelium, that gives a mixed bacterial infection of the adenoid. But when the inner distensible tube becomes swollen from infiltration within the outer indistensible tube, it must become choked and gangrene ensues. In mild cases exudation takes place slowly, and slow necrosis ensues. Spasm of the muscular wall produces quick necrosis.

The appendix is supplied by a single artery. An endarteritis once begun must end at length in obliteration, and in the death of the appendix from failure of blood-supply. In the milder cases, the incision should be in the trend of the external oblique, and but one inch and a half in length. The intestines may be rolled along over the finger tip until the appendix slips out. The base is turned in and the peritoneum brought together over it with catgut sutures. The after-disturbance is very slight, and it is difficult to keep patient in bed. In case of exudation the incision should be twice, in abscess three times, this length. A fifteen-volume solution of peroxide of hydrogen is used to irrigate the abscess cavity, and the drainage wick inserted.

Catarrhal appendicitis is a misnomer, as in all cases careful microscopic examination was made and the inflammation shown to be infectious exudative from the start. The prompt and invariable operative procedure urged is termed by some a fad, as was the removal of the appendages in the incipiency of that operation. Between the two procedures we must remember that, in the one we have a useful organ, the removal of which was attended with danger to the subject's life, and resulted in certain undesirable after effects, such as the termination of child-bearing; while in the appendix we have an entirely useless organ that may be removed without danger to life, and with positively no undesirable after effects.

Dr. Bernays, of St. Louis, said that both writers had attacked the subject from the only logical standpoint—the pathology. Dr. Morris had gone the further in taking cognizance of the bacteriological element. The results of operative treatment, as shown by Dr. Morris's mortality of four in forty-eight cases, of Dr. Murphy's seven in the first hundred, and his own statistics, ten in sixty-two cases, showed the great advantage of that course. The previous use of opium makes the prognosis of operation bad.

Dr. Frank, of Chicago, was accustomed to peel back the peritoneum, and after amputation of the appendix, to draw it down and, puckering it with a ligature, shut off the stump.

Dr. Cushing had had personal experience of appendicitis years ago, and the memory is still a nightmare. So-called catarrhal appendicitis is usually left until too late for operation, and then follows death. He believed the incision is entirely free from danger, and is not sure that it were not better for us all to have the appendix removed.

Dr. Eliza Mosher related the case of appendicitis following rubbing of the intestines after a large enema.

Dr. Murphy had found either pus or gangrene in all of his cases but one.

Habits of Posture a Cause of Deformity and Displacement of the Uterus, was the title of the concluding paper of the session, read by Dr. Eliza M. Mosher, of Brooklyn, N. Y. The brim of the pelvis was set at such an angle with the horizontal plane that the line of gravity of

the super-imposed viscera fell without the pelvis, in front of the pubes; and any sudden effort tended to push the uterus against the pubic arch. If this angle were lessened by habits of posture, in either sitting or walking, the line, as was demonstrated upon model, would fall within the pelvis and tend to retroversions and retroflexions if extreme, to anteflexions if less marked. The ideas of the paper were very aptly illustrated by models and drawings.

At the conclusion of the paper the hour for adjournment had arrived, and with an expression of congratulation and indebtedness to the presiding officer, the section dissolved.

SECTION ON OBSTETRICS.

Fourth Day, Friday, September 8th.

Puerperal Infection.—Dr. Edward A. Ayers, of New York, read a paper on this subject. He said our views to day as to the treatment of puerperal infection are in a great state of confusion. A dozen years ago the main line of treatment was that of general systemic remedies, such as alcohol, morphine, cathartics, and external applications. In a short while a recognition of the germ character of the disease led to the use of intra-uterine and vaginal irrigation. The extent to which this method of treatment has been carried is a marvel, not to say a terror. Few doctors refused its aid, most doctors employed it to arrest the disease on suspicion, and many considered their cases neglected if an intra-uterine douche was not administered after delivery in every case.

Following in the train of this method is a list of failures to prevent or cure infection, and a startling number of deaths from mercuric poisoning, that have developed a strong opposition to local douching. The efforts to find something better than the old opium and whiskey treatment has given laparotomists an excuse for testing the merits of abdominal drainage, or exsections of purulent tissues in some form of this disease's varied pathology. There is a grave fault in most of the discussions of this subject, namely, the lack of pathological classification, by which we find in various cases of puerperal infection much greater differences than in many distinct diseases.

Puerperal infection, caused by unclean manipulation of the "examiner," or by abscess in the labia, or the vagina, or uterus, or tubes; or by germs present in the genital tract at the time of labor, as in gonorrhœa and possibly in purulent leucorrhœa, or a sloughing fibroid, or decomposing fœtus or placenta, or partially organized blood-clot, or placenta succenturiata, or uterine rupture, etc., finds a footing somewhere along the genital tract from the vulva to the fundus uteri.

Let us surgically consider the question of local treatment. If a wound can be thoroughly irrigated and efficient drainage and protection secured, in the great majority of cases it will progress uninterruptedly to complete healing. Infection, starting on the surface of the vagina or endometrium, if there were but a superficial abrasion, would respond satisfactorily to irrigation. But suppose the labor has been long and severe; that the head of the child remained long in one place, pressing the uterine wall against the bony structure of the pelvis, with the consequent death of a portion of tissue *en masse*, if infection has obtained a place it will be present at the base of this loosening slough ere the dead mass has separated. Would you expect irrigation to cleanse the tissue beneath this slough? Or suppose the labor was very "laborious," followed by great muscular exhaustion of the uterus, mild relaxations occurring following the completion of the patient's toilet, with the formation of blood clot in the uterine cavity. This mass may be retained for days—I have so observed it—and become soft and foul-smelling, in short, decomposed. Irrigation will not render this mass, which may be as large as an orange, innocuous. Or suppose, following an exhausting labor, with threatened or supervened post-partum hemorrhage, cessation of bleeding is secured by the formation of thrombi in the sinuses of the uterus, nature's resource when the doctor fails to make efficient use of bimanual compression, if the germs have made their bed in these germ inns, how is irrigation going to kill them or drive them out? The thrombi penetrate the wall of the uterus. The antiseptic fluid flowing over the surface will not touch the inner mass. The presence of a placenta succenturiata will also, if unremoved, put an undeserved failure upon irrigation.

Let me briefly outline the indications for these various methods of local treatment.

1. A normal labor with steady and easy advance of the child, with complete removal of the placenta, followed by good contraction and retraction of the uterus, with no indication of a previously existing purulent condition, or of fibroids, but yet with infection, indicates that simple irrigation should do all that is possible, with perhaps the introduction of iodoform gauze, though I would prefer not to use it unless the discharge became purulent.

Use a fountain syringe, held not more than a foot or two above the patient's hips, with the patient lying on her back. A solution of bichloride, 1 to 4,000, at a temperature of 105° F., one to two quarts, should be used, followed by a pint or quart of freshly boiled water cooled sufficiently. I think my tube, which you see has a groove along the under side for exit of the fluid, is made of hard rubber and has a hole at the end as well as sides, permitting the stream to reach all parts at the fundus and without danger of forcing fluid through the tubes of the uterus, while the force is made so slight by keeping the syringe-bag low, and cannot possibly break, is preferable to Chamberlain's glass tube. The indication for repeated irrigation must be the rise of temperature. If the symptoms do not promptly subside, I would use iodoform gauze following irrigation.

2. A labor history that indicated prolonged pressure of the head would suggest possible gangrenous sloughing, and would call for the use of iodoform gauze from the start, to aid drainage, stimulate repair, and lessen decomposition.

3. A history of post-partum hemorrhage, or of torn placenta, with the presence of unusually large shreds of tissue in the lochial discharge, would call for an exploration of the uterine cavity. Putting the patient in Sims's position, a large blunt curette should be used in conjunction with irrigation, and the question answered: "Is débris present?" A thorough curettement followed by the introduction of iodoform gauze would be indicated.

4. A case where, on examination, the uterus is found to be relaxed, soft, "doughy," pitting on pressure, with a very offensive discharge, very purulent in character, and with general symptoms of high fever, profuse sweats, and great prostration, indicates purulent infiltration of the body of the uterus. From a theoretical stand point it may be said with assurance that intra-uterine irrigation will do nothing but possibly lower the temperature a little for a half hour. Pus is present throughout the connective and muscular tissues of the body of the uterus.

Irrigation of the cavity cannot possibly reach it. As well expect a stream of water flowing over the mammary gland, the seat of many abscesses, to wash away the pus within.

Post mortem examination of such cases shows pockets of pus dispersed throughout the muscular tissue that have no outlet into the uterine cavity. What resources have we in such cases for cure? General supportive treatment through the long weeks of struggle, or, may we not declare in favor of abdominal hysterectomy? In any other part of the body we would employ, in such a condition, multiple incisions with the introduction of drainage-tubes. We cannot do that here; it is possible to remove the diseased mass altogether.

A resolution of thanks to the President of the section was passed unanimously. Dr. Mitchell gave credit for the success of the section to the English- and Spanish-speaking secretaries, Drs. Hugh Hamilton and J. J. Castellanos. Dr. Hamilton said a large proportion

of the forty-seven papers had been read whose titles had appeared in the programme. All had been of high quality.

The section adjourned.

SECTION ON DISEASES OF THE MIND AND NERVOUS SYSTEM.

THIRD DAY, THURSDAY, SEPTEMBER 7TH.

Hypnotism: Does It Menace Public Weal?—DR. F. C. VALENTINE, of New York, read a paper on this subject, in which he stated that: 1. The therapeutic possibilities of hypnotism are not denied. A patient who persuades himself, or is persuaded, that he can be cured by the hypnotic influence, is as well or better cured than by drugs or appliances that do not appeal to his view of the case. 2. The hypnotic state should never be allowed a status in law or morals. While it is certainly better that a hundred rogues escape than that an innocent being be punished, there is no conceivable human mind that can be induced by hypnotic suggestion to do what its owner knows to be wrong. Those "moral defectives" who cannot distinguish right from wrong are proper subjects for the insane asylum. It must be clearly understood that no one can be hypnotized without his own fullest consent and co-operation; consequently any law of the land, or even unwritten code of morals, violated while under the alleged "influence" is as punishable as if committed in full independent possession of the mental faculties.

With this view everywhere accepted and established, hypnotism will no longer be a menace to public weal.

DR. C. G. COMEGYS, of Cincinnati, asked if in hypnotic states we have not an abeyance of the voluntary power. He thought the condition was allied to the dream-life, and that a man is as irresponsible in his dreams as when in the hypnotic state.

DR. MILLS, of Philadelphia, said that the paper seemed to him an illogical treatment of the subject, and contained many contradictory statements, which he pointed out *in extenso*. It would be unfortunate both for law and morals if hypnotism were made an excuse or defence for crime.

DR. BROWER, of Chicago, agreed with the criticism and views of Dr. Mills. In his experience there were extremely few susceptible to the influence of hypnotism. He thought that we can no more formulate any law controlling all cases of alleged hypnotism than we can in regard to all cases of insanity.

DR. A. B. RICHARDSON, of Columbus, O., believed there was a therapeutic value in hypnotism. Its indiscriminate use was dangerous to society. Public exhibition was a crime against public policy, and its practice should be limited to physicians.

DR. GRAEME HAMMOND, of New York, had concluded that foreigners were the more susceptible subjects. He discarded the use of hypnotism to a great extent. He had only noted some amelioration of symptoms, but no cure. He had noticed that the most susceptible people were mentally defective.

DR. JUAN PADILLA, of Guatemala, Mexico, believed that the writer of the paper had not sufficiently demonstrated the advantages offered by hypnotism, not only as a therapeutic agent but likewise as a medium that might in certain judicial cases serve to ascertain the truth.

DR. C. H. HUGHES said that there could be no question as to the possibility of inducing hypnotism. It should not be used as a plea in extenuation or defence of crime. It would be important to note the method by which hypnotism was accomplished. He designated it by the term "Somnavolism," and defined it as a condition of the absence or subjection or abeyance of the volition due to the induced sleep state.

DR. VALENTINE, in closing the discussion, said that he had only presented his paper in abstract. He believed, however, that every patient who has been hypnotized has been humbugged, and that ere long hypnotism and works on the subject will be relegated to the galleries of ancient discarded medical curiosities.

The Discrimination between Ordinary Paretic Dementia and Tabes Dorsalis on the one hand, and Syphilitic, Cerebral, and Spinal Disease Simulating the Former.—This was the title of a paper read by Dr. E. C. Spitzka, of New York. It was discussed by Drs. Dercum and Mills.

The Treatment of Inebriety.—Dr. J. G. Reed, of Elmwood Place, O., read a paper upon this subject.

The following papers were read by title: "Disease of Inebriety," by T. D. Crothers, M.D., of Hartford; "The Traumatic Psychoneurosis, its Relations to Paranoia, Epilepsy, and Paretic Dementia," by J. G. Kiernan, M.D., of Chicago; "The Urine in Sexual Neurasthenia," by Charles L. Dana, M.D., of New York; "Suppurative Meningitis and Myelitis, with Exhibition of Specimens," by Graeme M. Hammond, M.D., of New York; "Chorea," by Charles Henry Brown, M.D., of New York; "Study of the Temperature in Twenty-five Cases of General Paralysis of the Insane," by Frederick Peterson, M.D., of New York; "The Present Status of Infantile Cerebral Palsies," by Frederick Peterson, M.D., of New York; "The Successful Management of Inebriety without Secrecy in Therapeutics," by C. H. Hughes, M.D., of St. Louis; "The Medical Treatment of Insanity," by Edward C. Mann, of Brooklyn, N. Y.; "Where the New-born Baby Learned to Suck," by C. A. F. Lindorme, M.D., of Atlanta; "The Influence of Alcohol upon the Human Powers and Constitution," by T. L. Wright, M.D., of Bellefontaine, O.; "Neuro-angio Paralysis and its Relation to Paretic Dementia," by Frank C. Hoyt, M.D., of Clarinda, Ia.; "Civil Service in American Hospitals for the Insane," by S. V. Clevenger, M.D., of Chicago; "La Renguera," by Daniel Guitterez y Arango, M.D., of Call, Cauca, Colombia; "The Nervous Symptoms of Storms," by Curran Pope, M.D., of Louisville; "A Peculiar Type of Vaso-motor Neurasthenia (the Pulsating Disease), with Report of an Operation for the Same," by Charles L. Dana, M.D., of New York; "Nutrition against Stimulation," by W. H. Maxson, M.D., of St. Louis; "The Study of Criminal Anthropology and Social Reform," by Abundio Aceves, M.D., of Guadalajara, Mexico.

To Prevent Rust on Surgical Needles.—Dr. Horace T. Hanks, of New York, writes: "I have found, formerly, much difficulty in keeping my needles always free from rust and sepsis. For a year, however, I have kept all my needles in pure 'lysol,' and am perfectly satisfied with the result. I place from thirty to fifty assorted needles, points upward, in a suitable small bottle—large mouth, and screw-top preferable—and then fill with lysol. When needles are to be used turn the lysol into another phial and the needles on to a plate, and select the ones required, returning lysol and needles to the original bottle when through. By this means I always have aseptic needles, free from rust, and a small bottle of germicide fluid if no other is at hand."

The Cure of Hay Fever.—The treatment of hay fever is subject to criticism such as comes to no other disease, namely, from societies of the sufferers themselves. It is interesting to note that the patients are not as enthusiastic over, and do not report such good results as a society of their medical advisers would be likely to do. The United States Hay Fever Association have recently held their annual meeting in Bethlehem, N. H., and listened to papers largely on the disease from the patients' point of view. It appears to be the general opinion that the only certain relief is to be found in the White Mountains, and that most therapeutic measures are of little or no use, and some of them harmful. The treatment by local cauterization in the nose is often of benefit, but the benefit is generally only partial and temporary.

Correspondence.

IRRIGATION OF THE COLON IN INFANTS.

To the Editor of the Medical Record.

Sir: The article under the above title, by Dr. J. H. Huddleston, in your issue of the 9th inst., appeared to me to be both timely and well written. Considering the value of this measure as an aid in the treatment of diarrhœal diseases far too little attention has been given it. I have found it applicable both in hospital and in private practice, and in no case where I have used it have I been disappointed. It is only an aid in the treatment, and can only be an adjunct to the regulation of diet and to internal medication, but it is a most valuable aid.

During the past season's work at the Seaside Hospital of the Sanitarium for Hebrew Children I employed it in almost every case of diarrhœal disease; certainly in every case of entero-colitis. I employed, at first, the saline solution in some cases; in others the solution of boric acid, and in still others, only clear, tepid water. After a rather lengthy trial, I set the others aside in favor of clear water, of a temperature of 75° to 80° F.

The apparatus was precisely the same as that employed by Dr. Huddleston, excepting that I used for larger children a No. 18 catheter. The position was, however, different. The child's clothing was loosened and drawn up out of the way. Then the child was laid upon its back, near the edge of the bed, its buttocks raised by a pillow protected by a rubber cloth. This cloth was, where it came under the child's body, covered with a folded diaper to prevent chilling contact. The lower end of the rubber cloth was then placed in a pail set upon the floor, thus forming a drain to carry away the discharges and to protect the floor.

The nurse then drew the child's limbs, covered with a thin blanket, to prevent undue exposure, up toward the body, and held them there. The catheter, anointed with vaseline, was inserted with a gentle rotary motion, and, as soon as the sphincters were passed the water was allowed to flow into the rectum. I found that by this simple procedure the doubling up of the tube, otherwise so frequent, was reduced to the minimum. The water distends the rectum moderately and allows of the free passage of the tube. The entire catheter was passed, and the water allowed to pass freely in and out, for I found that in every case, after the colon had become moderately distended, the water, and, in addition, fæces and mucus, or mucopus, were passed with considerable force. In every case the irrigation was continued until the water returned perfectly clear. In some cases the quantity used was as high as four quarts. If any of the fluid was retained it was quickly passed into the diaper after the child was put back to bed.

In no case did I meet with collapse, or anything approaching it. (I must admit, however, that where I thought the infant too weak to bear the irrigation, it was not employed till the child was sufficiently revived to receive the treatment.) On the contrary, the peevish became quiet, those who had not slept were soon able to get good, large doses of that best of restorers, and the movements decreased most gratifyingly in number and in the amount of mucus contained.

In addition to the treatment described above, the strictest attention was paid to diet and to internal medication.

The treatment may be employed in the patient's home just as well as in the dispensary or hospital.

The instruments required are so simple, and the cost so small, that there is no reason why the treatment should not be in more extensive use than it is.

Very truly yours,

F. Bierhoff, M.D.,
Physician to the Sanitarium for Hebrew Children.
170 West 126th Street.

INGROWING TOENAIL.

To the Editor of the Medical Record.

Sir: I have read with more than passing interest the article in the Record of September 2d, entitled "A Report of Twenty-three Cases of Ingrowing Toenail Operated upon by the Method of Anger," and am interested sufficiently to ask, Why such a troublesome operation in place of the old one of complete enucleation? According to this article more time is given to the operation, after-treatment, and healing, and more trouble caused (as is shown in Cases 13, 15, 17, 18, 21, and "three cases in which considerable discomfort was caused by a new piece of nail starting") than in the enucleation operation. With a little nitrous oxide gas, or the ether spray, antiseptic after-treatment with iodoform or icthyol, the entire removal of the offending toenail is effective and satisfactory. If the patient is fully able to liquidate for visits at so much each, and is not obliged to be at work, all good and well. But in this country, where the operation is done probably at a distance from my office, and the patient not seen again for six months or a year, I hardly think the new operation would be successful. I am in favor of all new ideas, if practicable, to all surgeons and all classes of patients, but I can see nothing practicable in a cutting and flap-and-stitching operation for the cure of ingrowing toenail.

Park Holland, M.D.
Hyattville, Wyo., September 9, 1893.

CODEINE POISONING.

To the Editor of the Medical Record.

Sir: In the Record of July 15th Dr. William Philip Spratling gives his experience with a case of "Codeine Poisoning," his patient, a woman, having taken sixteen one half-grain pills of codeine. He writes that he saw her "three hours after taking the pills;" that "she was awake, able to converse perfectly well, but was extremely restless and irritable;" that "she suffered greatly from intense irritation of the skin over the entire body. There was also marked hyperæsthesia."

H. C. Wood's "Therapeutics" contains reports of several clinical observers whose experience with toxic doses of the drug are so varied that a report of a recent case of mine may be of interest.

J. K——, aged thirty-eight, a well developed, robust man, had la grippe about two years ago. Following his sickness he had a troublesome cough, to relieve which, he had taken, at beginning, small doses of morphia sulph.; but had gradually increased the dose until he had become a slave to the drug, taking at times fifteen grains per diem.

A short time before I was called to attend him he had seen, in a pamphlet issued by Mercks, that codeine would cure the morphine habit, and had purchased a bottle containing one hundred one-half grains of McKesson & Robbins's codeine pills. He began by taking ten pills at 8 P.M., waiting until 8.30 P.M. without perceptible effect; he then took ten more, and at 9 P.M., the longing for the usual effect of morphine was so pressing that he took twenty more pills, making in all forty, equal to twenty grains of codeine. He then patiently waited for the tranquillity this antidote promised. Instead, at 10 P.M. he began to experience an intense burning along the spine and flexor muscles of the arms and lower extremities, whence it rapidly extended to every part of the body. I saw him at 11 P.M., found him very nervous and excited; eyes sparkling and staring; conjunctiva red and injected; indeed the whole body was as red as a boiled lobster. Skin looked puffy and œdematous. He was frantically going about the room vigorously rubbing himself with a moistened crash towel. Great vascular excitement; pulse, 130; respiration, 22; temperature, 99½° F.; pupils not contracted; experienced none of the effects of morphia. Begged me to give him an hypodermic of morphia.

Bathing the body with a solution of biborate of soda controlled in a measure the burning and itching, which continued until 2 A.M., when it gradually disappeared, leaving the skin hyperæsthetic for twenty four hours. There was at no time symptoms of opium poisoning. No nausea or vomiting. No contraction of pupils, no loss of co-ordination. He had for some time been reducing the quantity of morphia, so that he was taking about two grains three times a day (his statement), which must be taken *cum grano salis*.

The pills were made by the well-known firm of McKesson & Robbins, and contained one-half grain of codeine.

I have been giving a patient, sixty years of age, with diabetes, one of these pills three times a day, which causes him to be drowsy and to sleep soundly at night.

Very respectfully,

Z. J. LUSK, M.D.

WARSAW, N. Y., September 15, 1893.

THE TREATMENT OF DYSMENORRHŒA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Under the caption of a case of dysmenorrhœa I recently reported a case to the MEDICAL RECORD. I have received twenty-four valuable and interesting letters from various members of the profession in all parts of the country. This speaks well for the far-reaching distribution of the MEDICAL RECORD. . . . .

What has been the history of this case since my last date of writing? She went to Asbury Park for a diversion of six weeks. She bathed in the ocean, took chloralamid when necessary, and continued the albuminate of iron, also valerianate of zinc during the premonitory period, and even during the period itself. During the first period that followed her arrival here she had much pain, and passed a great quantity of membrane from the uterus (membranous dysmenorrhœa). The next period better, still painful, but more bearable. The improvement is gradual, but sure and encouraging. The membranous discharge was undoubtedly caused by the intra-uterine galvano-caustic to which she had been subjected. Almost always it is the case, so far as I have observed at Apostoli's Clinic and in my own work, that the result of electrical treatment does not manifest itself until some time after the discontinuance of the treatment. I have stopped the chloralamid, and she is taking nothing now but salipyrin—which is a useful and valuable synthetic production in many uterine troubles that have neuralgic and periodic symptoms—and the iron.

HORATIO R. BIGELOW, M.D.

PHILADELPHIA, September 18, 1893.

THE CASE OF IMPETIGO HERPETIFORMIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In a recent number of the MEDICAL RECORD I find the report of a case of "Impetigo Herpetiformis," by Dr. Herman, of Memphis. The remark is made there that it is the second case reported in America. This is not correct. The undersigned communicated a paper containing the details of a typical instance of that rare disease to the Ninth International Congress at Washington, as the "Transactions" of the same will show, and also published his case in the *Monatshefte f. prakt. Dermatologie*, in 1887. Another case, though not quite typical, is described by Dr. Sherwell, of Brooklyn, in the *Journal of Cutaneous and General Urinary Diseases*, 1889, p. 456.

If, by the way, the objective reader is justified in having a diagnosis upon the description of another, Dr. Herman's case is by no means an example of impetigo herpetiformis. This dermatosis does not begin with a vesicular eruption, but is from the start pustular in character, the typical arrangement in groups, the centre of which soon crusts over, the peripheral extension of the patches, the localization in certain characteristic places (genito-crural surfaces, anal folds, axillæ, elbows, breasts, navel, nails, etc.), is not alluded to in Dr. Herman's report. Nor is there ever any ulceration present, nor do elevated, or, indeed, any sort of scars ever form in impetigo herpetiformis. The favorable result of the treatment is surely very remarkable, as heretofore almost all cases had a fatal termination.

Still, Dr. Herman's case may, after all, be an example of that disease, as the woodcut and some points in the description suggest; but if it is, the writer has failed to convince the reader of the correctness of his diagnosis.

JOSEPH ZEISLER, M.D.,
Professor of Dermatology Northwestern University.

CHICAGO, ILL.

IS THERE A REAL NECESSITY FOR A NATIONAL HEALTH BILL?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your issue of September 16th I see a friend favoring the bill for a National Bureau of Health for certain things the bureau might do. It seems to me that all that could be done by the different State Boards of Health, provided the people wanted them to do so. A National Bureau of Health seems to be entirely foreign to American institutions. True, the United States represent a nation, and a great one too, but we must also remember every State of the Union is sovereign of its internal affairs, and not one of the fourty four States is without a State Board of Health, and if the above boards are made to answer the purpose for which they are created, and be under control of competent medical men, every State in the Union will be in an excellent sanitary condition, and in that case the United States can get on all right without any Secretary of Public Health. Practically, the nation cares only for one secretary, *i.e.* (Secretary of the Treasury). As to quarantine, there are already Federal laws on that subject, and some laymen already suspect us *causa nota*, for that bill is no more justified than a ministers' bill for a national bureau of religion. Unfortunately our profession has as many sects nearly as the Christian religions, and a passage of the medical bill would be a good stimulus for our clerical brothers, healers of the souls of men. Foreign governments have departments of religion, and the United States never had such a department, and probably will never have. As to the National Health Bureau bill, I trust the bill, if introduced in the Senate, will lie on the table till all the doctors of the country will agree.

Very truly,

GEORGE A. LURIA, M.D.

181 ELDRIDGE STREET, NEW YORK.

Nitrate of Aconitine in Facial Erysipelas.—Tison (*Sem. Méd.*, August 25, 1893) was first induced to use this remedy in 1888, and has employed it subsequently in every case of facial erysipelas which has come under his treatment. The results have been highly satisfactory, pain and other symptoms having been rapidly subdued, save in two instances, and in neither of these could the complications which arose be due to the treatment. Although the nitrate of aconitine is highly poisonous, and it may be objected to by some on this account, if used as now suggested the danger of untoward symptoms is very slight. The alkaloid is dissolved in a mixture of glycerine, alcohol, and distilled water, the mixture having the same specific gravity as water and containing 1 milligr. in 50 minims. Only 2 to 4 milligr. are required in any one case. The method of procedure is as follows: According to the condition of the stomach, either an emetic or a purgative is administered, immediately after which nitrate of aconitine is given in a mixture containing 1 milligr. for the twenty-hours' dosage. The affected part is painted with a saturated ethereal solution of camphor, which acts as an excellent sedative. When all signs of inflammation have subsided the part is washed with a solution of lysol.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 23, 1893.

	Cases.	Deaths.

Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

The New Law Regulating the Practice of Medicine in Kentucky.—Be it enacted by the General Assembly of the Commonwealth of Kentucky:

SECTION 1. It shall be the duty of the County Clerk of each county to purchase a book of suitable size, to be known as the "Medical Register" of the county, and to set apart one full page for the registration of each physician; and when any physician shall die or remove from the county, he shall make a note of the same at the bottom of the page; and said clerk shall, on the first day of January in each year, transmit to the office of the State Board of Health a duly certified list of the physicians of said county registered under this law, together with such other information as is hereinafter required, and perform such other duties as are required by this law; and such clerk shall receive the sum of fifty cents from each physician so registered, which shall be his full compensation for all the duties required under this law.

SECT. 2. It shall be unlawful for any person to practise medicine, in any of its branches, within the limits of this State, who has not exhibited and registered in the County Clerk's office of the county in which he resides his authority for so practising medicine as herein prescribed, together with his age, address, place of birth, and the school or system of medicine to which he proposes to belong; and the person so registering shall subscribe and verify by oath, before such clerk, an affidavit containing such facts, which, if wilfully false, shall subject the affiant to conviction and punishment for perjury.

SECT. 3. Authority to practise medicine under this law shall be a certificate from the State Board of Health, and said Board shall, upon application, issue a certificate to any reputable physician who is practising, or who desires to begin the practice of medicine in this State, who possesses any of the following qualifications: First. A diploma from a reputable medical college legally chartered under the laws of this State. Second. A diploma from a reputable and legally chartered medical college of some other State or country, indorsed as such by the State Board of Health. Third. Satisfactory evidence from the person claiming the same that such person was reputably and honorably engaged in the practice of medicine in this State prior to February 23, 1864. Applicants may present their credentials by mail or proxy, and the Board shall issue its certificates to such applicants as are entitled thereto as though the applicant was present. All certificates shall be signed by the President and Secretary, and attested by the seal of the Board, and not more than two dollars shall be charged for any certificate.

SECT. 4. Nothing in this law shall be construed as to authorize any itinerant doctor to register or to practise medicine in any county in this State.

SECT. 5. The State Board of Health may refuse to issue the certificate provided for in section three of this article to any individual guilty of grossly unprofessional conduct of a character likely to deceive or defraud the public, and it may, after due notice and hearing, revoke such certificates for like cause. In all cases of refusal or revocation, the applicant may appeal to the Governor, who may affirm or overrule the decision of the Board, and this decision shall be final.

SECT. 6. Nothing in this law shall be so construed as to discriminate against any peculiar school or system of medicine, or to prohibit women from practising midwifery, or to prohibit gratuitous services in case of emergency; nor shall this law apply to commissioned surgeons of the United States Army, Navy, or Marine Hospital Service, or to legally qualified physicians of another State, called to see a particular case or family, but who does not open an office or appoint any place in this State where he or she may meet patients or receive calls.

SECT. 7. It shall be the duty of the State and local boards of health to bring to the attention of the courts any violations of the provisions of this law within their respective jurisdictions.

SECT. 8. Any person living in this State, or any person coming into this State, who shall practise medicine, or attempt to practise medicine in any of its branches, or who shall perform, or attempt to perform, any surgical operation for or upon any person within the limits of this State, for reward or compensation, in violation of the provisions of this law, shall, upon conviction thereof, be fined fifty dollars, and upon each and every subsequent conviction shall be fined one hundred dollars and imprisoned thirty days, or either or both, in the discretion of the jury; and in no case, where any provision of this law has been violated, shall the person so violating be entitled to receive compensation for services rendered. To open an office for such purpose, or to announce to the public in any other way a readiness to practise medicine in any county, shall be to engage in the practice of medicine within the meaning of this law.

Approved, April 10, 1893.

Another Telling Epitaph. — William B. Savage, M D., of East Islip, L. I., writes: The perusal of a seasonable epitaph in your issue of September 2d, calls to mind one that I came across in the old churchyard at Cheltenham, England. It seems that an old physician, accompanied by his three daughters, went to Cheltenham to test the efficacy of the waters for which it was famed at that time. While sojourning there his three daughters died. The old gentleman, feeling that he was not long for this world, drew up his will, in which he left instructions that the following epitaph should be inscribed upon his tombstone:

> "Here lies I, and my three daughters,
> All through drinking these ere Cheltenham Waters.
> Had we stuck to Epsom Salts,
> We shouldn't have been lying in these ere Vaults."

Mistakes in Diagnosis.—It was stated not long ago in the House of Commons that four hundred and fifty persons had been admitted last year to fever and small-pox hospitals in London on physicians' certificates, who were afterward found not to be suffering from contagious diseases. Of this number ninety-seven died, but the death was in every case, as the President of the Local Government Board maintained, due to the disease with which the patient was at the time suffering, and not from any cause which was related to the removal.

What Woman Can Do.—A Kentucky woman who concluded her medical studies this spring brought home in one arm her diploma and in the other her week-old babe. Another woman, in Kansas, not long ago celebrated her election as town mayor by giving birth to a child on the same day. Which either proves the superiority of woman over man by way of versatility and endurance, or it may be accepted as a protest by nature against modern attempts to set insuperable barriers.

MYXŒDEMA—THE FUNCTIONS OF THE THYROID GLAND, AND THE PRESENT METHOD OF TREATMENT OF MYXŒDEMA.*

BY FRANCIS P. KINNICUTT, M.D.,

PHYSICIAN TO ST. LUKE'S HOSPITAL AND THE PRESBYTERIAN HOSPITAL, NEW YORK.

THE nature of thyroid tissue, its distribution in the body, its relation to other gland tissue and to the pituitary body, and finally the functions of the thyroid gland, have been the subject of investigation by numerous observers, especially in the last decade.

Victor Horsley, in a critical and historical review of the functions of the thyroid gland, published in 1891,[1] concludes from all accessible evidence that the thyroid gland is a structure essentially connected with the metabolism of the blood and tissues; that in fulfilment of its functions it is hæmopoietic both directly and indirectly, and that it forms, that is, secretes, from the blood a colloidal substance which is transmitted via the lymphatics from the acini of the gland to the circulation.

Evidence that the thyroid gland is directly hæmopoietic rests mainly, 1st, upon the observations of Credé [2] and Zesas,[3] to the effect that hypertrophy of the thyroid followed experimental extirpation of the spleen in animals, together with an increase in the number of white cells and a diminution in that of the red corpuscles. Later the leucocytosis disappeared. Horsley also noted, clinically, hypertrophy of the spleen following experimental thyroidectomy, a condition verified post mortem;[4] 2d, upon the anæmia associated with cachexia strumapriva. Horsley observed in experimental thyroidectomy in monkeys [5] a continuous diminution in the red blood-corpuscles subsequent to the removal of the gland, with an increase in the leucocytes, but only for a comparatively limited period, when the decrease in the former ceased and an oligæmic equilibrium was established and maintained until death. He found, moreover,[6] definite lymphoid tissue of a distinctly splenic character. Also, by an enumeration of the leucocytes in the thyroid arteries and veins, respectively, he was able to show that they were in a greater proportion in the latter, and that this proportion was greater than existed in the vessels of the limbs. In the absence of further evidence on this point, a directly hæmopoietic function of the thyroid gland cannot be considered as yet proven.

The theory of an indirect hæmopoietic function is based chiefly upon the observations of the condition of the blood following thyroidectomy. The changes noted by various observers (Herzen, Hofrichter, Albertoni and Tizzoni, and others) [7] are increased venosity, marked diminution in the oxygen of the arterial blood, even to the degree of its falling below that in the veins, and the presence of mucin in the blood plasma.

Albertoni and Tizzoni were able to demonstrate that the deficient oxygenation was not due to mechanical interference with the respiratory act, by obtaining the same results in dogs which were tracheotomized after thyroidectomy. Horsley justly remarks that such changes gravely "altering the constitution and functional activity of the blood, must evoke a considerable degree of anæmia both by destructive changes in the fluid itself and by the effect which it, thus altered, necessarily exerts on the blood-forming tissues, for example the marrow.[8] Further observations on these points are to be desired.

That the thyroid gland forms or secretes a colloidal substance, which is transmitted via the lymphatics from the acini of the gland to the circulation, was first apparently demonstrated by King,[9] and later confirmed by Langendorff,[10] Kohlrausch,[11] Horsley,[8] and others.

King's interesting contribution "On the Structure and Adaptations of the Thyroid Gland," was published in 1836, with some additional notes on the same subject by Sir Astley Cooper. The former was able to demonstrate the introduction of the peculiar secretion of the gland into the lymphatics, by expelling its contents by gentle and repeated compressions into the lymphatics of the surface, and there coagulating the fluid *in situ*. He further considers the sources in the living body of compression and muscular manipulation of the gland, viz., the movements of the larynx both vertically and toward the spine, the distention of the œsophagus in the descent of food, and finally the action of the muscles investing the gland, the sterno-hyoid, the omo hyoid, and sterno-thyroid. It is of interest to note that in speaking of extreme fibroid atrophy of the gland, which he had observed in a particular case, he states that "the peculiarities of the individual were fully sufficient to indicate the importance of the defective part."

King, therefore, not only recognized the importance of the functions of the thyroid gland, but possibly had observed the clinical picture which is now known under the name of myxœdema.

Sir Astley Cooper's notes contain a chemical analysis by Babington of the thyroid secretion, from which the latter was led to believe that it was largely an albuminous fluid.[9] Passing over other early analyses of this secretion, the chemical investigation of its nature by Langendorff, which is one of the most recent, may be mentioned.[10] He examined the colloidal contents of the thyroid follicles with various reagents, and finally, from their behavior with acetic acid, concluded that mucin is not present. The various tests for albumin confirmed the conclusion that the colloid material either consists of albumin or that it is the chief component. Concerning the nature of the single or preponderating albumin present, he states that it is not alkali-albumin, unless, as Virchow suggests, it be alkali-albumin modified by a large percentage of sodium chloride. He failed in his analysis to find an appreciable quantity of globulin. The contents of the lymph-spaces were found to be identical with the colloid substance of the follicles. The course of the secretion beyond the lymph-spaces he was unable to demonstrate, and he advances the view that it remains in the gland (in its follicles and lymph-spaces) and becomes dehydrated, and that the unique function of the thyroid gland is to purge the blood of useless or injurious substances.

Whether we accept Horsley's view that the thyroid gland possesses a twofold function, viz., "a hæmatogenous and a mucin-excreting one," or we reject the former and believe that the gland "secretes a substance which, entering the circulation, prevents an auto-intoxication by transforming the toxic products of metabolism into easily eliminated bodies, or by directly neutralizing these products," a view at present held by many, the vital importance of a physiological activity of its functions is to-day recognized by a great majority of observers.

* Read before the Association of American Physicians at Washington, June, 1893.

Evidence of the correctness of this belief is found:

First. In the developmental history of the thyroid gland.

Horsley has shown that in the human fœtus the epithelial cylinders of the gland begin their secretory functions from the sixth to the eighth month.[1] Huschke[12] found that its proportion to the weight of the body in the new-born was that of 1 to 400 to 243, 1 to 1,166 at the end of the third week, 1 to 1,800 in the adult. In other words, its functions are well developed in intra-uterine life and early infancy, at a period when metabolism is especially active. Again, in intra-uterine cretinism, which is now well recognized, and in which the cretinic and myxœdematous cachexia is far advanced at birth, as a rule no trace of the thyroid gland is found.

Second. In the ultimately fatal cachexia (cachexia strumapriva) which follows total extirpation of the thyroid gland in many species of animals. The dependence of the symptoms of cachexia strumapriva upon injuries inflicted in thyroidectomy upon the laryngeal nerves and the cervical sympathetic and vagus, a view, first advanced by Munk, has been shown to be incorrect.[13] A series of experimental investigations by Ewald, Herzen, Horsley, and others have demonstrated that these nerves can be subjected to every kind of irritation without producing any of the symptoms of this cachexia.

Third. In the similar cachexia which, in a large number of cases has been observed to occur after complete thyroidectomy in man.

Fourth. In the clinical events which accompany and follow gradual morbid changes with loss of function in the thyroid gland, constituting a well-defined disease, to which the name of myxœdema has been given by Dr. Ord. The dependence of myxœdema upon such changes has received the most positive demonstration. In the very admirable and elaborate investigation of the subject of myxœdema by a committee of the Clinical Society of London,[14] extending over the period from 1883 to 1888, in thirteen autopsies in patients dying of this disease, in which the thyroid gland was examined, striking and uniform disease of the gland was found in every instance; the pathological change consisting in the replacement of the glandular structure by fibroid tissue. Moreover, all clinical and pathological observations up to the present date indicate that this is the one condition common to all cases of this disease.

Further valuable evidence of the active function of the gland is found in the recognition, in partial thyroidectomy, of an hypertrophy of the portion of the gland not removed; in a similar hypertrophy of the accessory glands or thyroid tissue in cases in which complete thyroidectomy has been performed experimentally in animals; and finally, in the amelioration or arrest of sporadic cretinism, cachexia strumapriva, and myxœdema, which at present are regarded as practically identical, either by transplantation in animals or human beings, or by the injection of, or feeding with, a thyroid extract.

It will be of interest to refer briefly to a few of the experimental investigations upon which these observations are based.

Hofmeister,[15] removed the thyroid gland in a number of puppies of five to sixteen weeks of age, allowing the accessory glands to remain. The usual fatal cachexia was averted, and the animals were killed at intervals of one to seven months after operation, apparently in good health. At the autopsies a marked retardation of bony growth, as compared to that of the control animals, was found. The long bones and those of the pelvis were most affected, those of the cranium and jaw, least. The length of the tibial diaphysis, two and one-half months after operation, measured only fifty-eight millimetres as compared with seventy-seven millimetres in the controls. There was also delay in the ossification of the epiphyseal lines and the synostoses. The sella turcica was unusually broad, and the hypophysis cerebri (pituitary body) was noticeably hypertrophied. There was also a follicular hypertrophy of the ovaries. The retention of the accessory bodies, it is seen, was able to avert a fatal issue in extirpation of the thyroid. The presumably increased activity of their functions was not, however, sufficient to fully compensate for the loss of the gland.

Halsted, in a series of very interesting experiments, was able to demonstrate that many times the normal weight of the thyroid gland could be removed from the human subject by performing partial thyroidectomies at intervals of several months; in other words, that a very marked and rapid hypertrophy of the portion of the gland left occurred.[16]

In transplantation experiments, whenever successful fixation of the gland has been obtained, amelioration of the cachexia has occurred. Among the earliest experimental workers in this field may be mentioned Schiff, Kocher, and Bircher.

A case of great interest of this kind has been reported very recently by Gibson.[17] Apparent recovery from sporadic cretinism followed the grafting of one lobe of the thyroid gland of a sheep into the anterior abdominal wall, and a second lobe into the abdominal cavity.

Gley's experiments on rabbits gave the following results: The removal of both the thyroid gland and accessory bodies was followed by death. Removal of the thyroid gland alone resulted in hypertrophy of the accessory bodies, with recovery. Removal of the accessory bodies alone was followed by no unfavorable results. Gley also found that extirpation of the spleen added neither to the rapidity of death nor to the severity of the symptoms. Removal of the hypophysis cerebri (pituitary body) produced symptoms similar to those observed after extirpation of the thyroid, and injection of thyroid juice cured or ameliorated the effects of such removal.[18]

Upon the gradually acquired knowledge of the vital importance of a physiological activity of the functions of the thyroid gland rests the evolution of the present method of treatment of the diseases in which these functions are impaired or lost, viz., myxœdema, sporadic cretinism, and cachexia strumapriva.

An historical summary of the steps in this evolution is contained in a paper by me in the "Transactions of the Association of American Physicians" of the present year. I shall therefore take up the narrative at the date (October, 1891) of the introduction of hypodermic injections of an extract of the thyroid gland in the treatment of myxœdema, by Dr. George Murray, of Newcastle, England.[19]

At about the same time, Brown-Séquard and D'Arsonval[20] had suggested its use, but to Dr. Murray is due the honor of the practical application of the method and a demonstration of its success. Dr. Murray's first case, one of well-marked myxœdema, was treated with the most brilliant results by injections of a glycerine extract of the thyroid gland of a sheep, and others in rapid succession were treated similarly by him, with equally remarkable benefit.

Numerous English clinicians quickly followed in his footsteps, and up to the present date sixty-seven cases of myxœdema and sporadic cretinism have been reported, of which a brief summary is appended, in which a similar method of treatment or a modification of it to be described, has been followed by equally brilliant results. In these cases, with two exceptions, the myxœdematous symptoms not only have been greatly ameliorated, but in many they have disappeared, and individuals who had become apparently hopeless invalids, with degeneration of mental and physical vigor, have been restored to lives of comfort, and in some instances of usefulness.

A further evolution of this treatment is due to Dr. Mackenzie, of London, and Dr. Fox, of Plymouth, England.[21] The disadvantages of injections of thyroid extract consist in the not infrequent production of abscesses and indurated swellings, presumably due to the use of not absolutely aseptic preparations, or to a technique not without reproach, and the occasional occurrence of rather alarming symptoms immediately following the introduction of the extract into the economy—the result, Dr. Murray believes, of a too rapid injection.

By a curious coincidence, the discovery was made simultaneously by Dr. Mackenzie and Dr. Fox that the administration by the mouth of the thyroid gland possessed all the advantages, without any of the disadvantages, of injections of the extract.

The raw, minced glands of a sheep, prepared in various ways to make them as palatable as possible, were given at intervals of a day or two, to myxœdematous patients, with results similar to those described from the use of injections.

Further modifications of this treatment consist in the employment of the slightly cooked gland, and of the extract in a dry state, in the form of tablets.[22]

As the symptomatology and treatment of myxœdema, in addition to a consideration of the functions of the thyroid gland, have been assigned to me in the present discussion, I have thought that the former might be best illustrated by the clinical history of a typical case* of the disease which has been under my personal observation for several months. It is as follows:

S. W——, housewife, forty-nine years of age, was admitted to the wards of St. Luke's Hospital, October 26, 1892.

Family Antecedents.—There is no evidence of the existence of myxœdema either in direct or collateral lines. The patient's father died of heart disease, her mother of cancer of the breast.

Personal History.—Menstruation appeared at fifteen years; the function was exceptionally normal throughout its entire period. The menopause occurred at forty years. There have been two births, at an interval of three years, the last twenty-five years ago, and no miscarriages. The patient's life has been throughout a tranquil and happy one. Exceptionally good health was enjoyed until about twelve years ago, when a slight impairment of hearing was noticed by patient, which has gradually increased up to the present time. At about the same period the skin began to grow rough and scaly, and this symptom was more noticeable during the winter months. Very gradually the skin became dry and wrinkled, and there was little or no perspiration even in warm weather. Eight years ago, a slight hesitancy in speech was appreciable, and gradually it became an effort to talk. At about the same time the hair began to fall out and no new growth followed. A little later a puffiness of the face, particularly about the eyes, was noticeable, which gradually increased until two years ago; since this date this symptom is said to have remained stationary. Six years ago, locomotion became impaired, increased size of the feet was noticed, and larger and larger shoes gradually have been required. An apparent thickness of the tongue and enlargement of the hands, with brittleness of the nails, were next noted. During the past two years there has been some impairment of memory. In the past year, locomotion gradually has become very difficult, and of late the patient has been able neither to stand nor sit up without support, and has been comfortable only when in bed. The eyesight, the sense of smell and of taste, apparently have remained unaffected.

A study of the family and personal history of the patient throws little light upon the etiology of the disease. An inherited predisposition, catamenial disturbance, excessive child-bearing or lactation, rapidly succeeding pregnancies, which have been regarded as possible factors in the causation of myxœdema, are all absent in the present case. This is also true as regards prolonged mental worry, and specific or exhausting illnesses. The age at which the first symptoms were developed, corresponds with that of a large proportion of cases of myxœdema, and the nature of the symptoms and the slow progress of the disease are very characteristic.

Condition on Admission to Hospital.—The patient presents the characteristic appearance of an advanced case of myxœdema. The physiognomy is dull and mask-like from the effacement of the natural lines of the face. The features are broad and coarse. The face is enlarged in all its dimensions, especially in its transverse diameter. Its skin is dry, wrinkled, and markedly thickened, especially over the forehead. Over the cheeks and bridge of the nose there is a rather sharply defined pinkish patch, in strong contrast with the porcelain-like hue of the orbital area. The lower eyelids are swollen and baggy, and a puffiness of the tissues immediately below is very noticeable. The whole nose is swollen and the bridge flattened. The hair of the eyebrows and eyelashes is short and scanty. The apertures of the eyes are narrowed and the space between them is broadened. The mouth is widened transversely. The lips are swollen, especially the lower one, which is pendulous, everted, and of a violet hue. There is a constant dribbling of saliva. The mucous membrane of the mouth is evidently thickened, the tongue markedly so. The gums are swollen and spongy. The teeth which remain, sixteen in number, are in various stages of decay. The uvula is normal in appearance. The scalp is covered with a thick mass of dry scales, and

Fig. 1.—Immediately before Treatment.

the hair is dry, ragged, brittle, and scanty. There is an extensive tumefaction of the subcutaneous tissues directly above the right ear. The skin of the trunk and extremities, particularly of the hands and feet, is excessively dry, thickened, and scaly. There is an entire absence of hair in the axillæ and about the pubes. The hands and feet are markedly thickened and broadened. The nails are brittle, marked with longitudinal striæ, and the crescents are absent. There is slight pitting on firm pressure over the dorsal surface of the feet. Circumscribed tumefactions are present in both supra-clavicular regions, this sign being more marked on the right side. The speech is monotonous, slow, and of a character which must be heard to be fully appreciated. It is characteristically similar in all the cases of myxœdema which have come under my notice. A slowness in apprehension, thought, and action, is very appreciable, but the mental process, finally, is correctly performed. There is some impairment of memory, especially for recent events, and the patient is emotional.

There is a paresis of the nuchal muscles, of the muscles of the trunk and of the extremities. The head tends to fall forward, the patient sits up with great difficulty, and cannot stand or walk without much assistance. There is, in addition, a certain amount of inco-ordination of the muscles of the lower extremities. Dynamic register of grip: right, 71, left, 68. There is a distinct diminution in the reaction to the faradic current in the muscles of

* The case was kindly referred to me by Dr. Elizabeth Cushier, of this city.

the extremities. The reaction of degeneration to the galvanic current is not present. Cutaneous sensation is in all respects apparently normal. Retardation of sensation is absent. The deep reflexes are normal, the cutaneous diminished. There is incontinence of urine and obstinate constipation, with from time to time involuntary movements of the bowels. The urine has a low specific gravity (1.012 to 1.014) and is, as a rule, alkaline in reaction. It contains a trace of albumin. Sugar is absent. Amorphous and triple phosphates are very constantly present. The average excretion of urea is four grains to the ounce. The eyesight is apparently normal, as are also the senses of taste and smell. The hearing is markedly impaired. The voice is only heard when greatly raised and the mouth placed to the ear.

An examination kindly made by Dr. Charles S. Bull is as follows: Tuning-fork heard equally well in both ears. Watch slightly better in left ear, but heard only when in contact with auricle. Membrana tympani in each ear shows the usual signs of chronic catarrhal proliferous otitis. They are sunken and altered in curvature, particularly in Shrapnell's membrane. Handle of malleus very prominent in both ears. Light spot somewhat diffused. Eustachian tubes readily opened by politzerization. There is chronic antero posterior hypertrophic rhinitis, which extends well down into pharynx.

The temperature is constantly subnormal, the range being from 96° to 97.5° F. (mouth). In connection with the low temperature noted, it may be stated that the patient says she is always cold, even in hot weather; moreover, that there is never any moisture of the skin at any season of the year.

The pulse averages about 70, and is without tension. There is no appreciable thickening of walls of arteries.

Examination of the blood shows good rouleau formation. The red corpuscles are of average size and shape. Hæmoglobin, 48 per cent.; red cells, 3,160,000 per c.mm.; white, 4,680 per c.mm. The white cells are absolutely, but not much relatively, reduced. Stained specimens show various forms of white cells in their normal proportion to each other. (Dr. Southworth.)

Physical examination gives negative results as regards the lungs, liver, and spleen. The first sound of the heart is feeble; there is an absence of murmurs. There is no enlargement of the superficial glands. There are a number of deeply pigmented moles scattered over the surface of the trunk, extremities, and neck. The thyroid gland is not palpable; the fulness of the neck, however, interferes with a satisfactory examination.

The symptoms and signs presented by the patient form an almost classical picture of myxœdema. The long duration of the disease, twelve years, the gradual evolution of symptoms, the final development of the stage of degeneration, which justly occasioned doubt, on the admission of the patient to the hospital, of a much further prolongation of life, constitute a very interesting and instructive study.

As the history of the case is intended to embrace the symptomatology of myxœdema, I shall call attention only to those symptoms which were not observed in the present instance, but which have been reported as being present with more or less frequency in other cases, and to those which were noted and which hitherto either have not been described, or have been mentioned as of infrequent occurrence.

Insanity (melancholia, dementia) has been noted not infrequently associated with myxœdema, and at least one case of melancholia with epilepsy has been reported.[25]

Its possible dependence in such instances upon the myxœdematous state, apparently had not been entertained previous to the results observed by the present method of treatment of myxœdema. A further reference to this point will be made later.

In the present case no disturbance of the psychical functions other than that mentioned, existed. Retardation of sensation, which has been observed in about half of the recorded cases of myxœdema, was not present. In regard to this symptom, it may be mentioned that in many cases the note of the reception of the sensation may have been deferred by the hebetude of the patient. Incontinence of urine, which was observed in the present case, has occasionally been noted in others. Incontinence of fæces, which was also present, has not been reported hitherto, so far as I am aware.

The case seemed an exceptionally favorable one, from its long duration and the advanced and degenerative stage which it had reached, for a study of the effect of treatment by feeding with the thyroid gland.

Feeding, rather than injections of the extract, was determined upon, on the ground that any benefit which might ensue would be even of greater interest. In spite of Mackenzie's reported results, much scepticism was felt of the possibility of a remedial action of a gland secretion, which could only enter the blood or lymph channels after its introduction into the stomach and its exposure to the action of the gastric juice.

From the date of admission to the hospital until November 26th, one month, the patient was confined to her bed without treatment of any kind, that the effect of an equable temperature and simple hygienic measures might be observed. During this period her condition remained without appreciable change. The temperature (mouth), taken at intervals of four hours except during sleep, presented slight diurnal variations, the range as a rule being between 96° and 97° F. and a fraction.,

On November 26th, a sandwich of what at the time was supposed to consist of the minced raw thyroid gland of a sheep, was given and repeated on the six succeeding days. Its ingestion was not followed by the slightest variation in the temperature curve, the percentage excretion of urea, or in any subjective sensation. It was then discovered that a large lymphatic gland, taken from the tissues immediately contiguous to the site of the thyroid, had been used instead of the latter.

On December 10th, half a drachm of the minced raw thyroid gland of a sheep in an equal amount of glycerine,* was given by the mouth. The temperature, pulse, and urea excretion were alike unaffected by its administration. A like amount was given on the four succeeding days, with similar results. The only subjective sensation complained of by the patient during this period was a slight feeling of dizziness.

On December 15th, one drachm of the raw minced gland was administered in a similar amount of glycerine. The pulse, respirations, and temperature immediately previous were, 72, 16, and 97° F., respectively. Five hours later the pulse and temperature were 76 and 98.5° F., the respirations remaining unaffected. The patient expressed herself as feeling no discomfort of any kind. A similar amount of the gland, equivalent to one lobe, was given daily, with a single omission, until January 7th, twenty-three days.

The temperature range during this period was between 98° and 100½° F., the higher point being reached in the afternoon; the pulse rose to 96 on the second day, and constantly ranged from this date between 90 and 106. It is seen that with the administration of the increased dose the pulse and temperature were immediately affected. The urea excretion also rose directly from 3½ grains to the ounce to 8 grains.

On December 29th, nineteen days after the first dose of the gland had been given, and two weeks after its use in larger amounts, the improvement in the patient's condition was very striking. The expression of the face had changed very remarkably; the swelling of the tissues had greatly diminished, the bagginess of the lower eyelids had disappeared, the lower lip was no longer everted and swollen, the saliva had ceased to dribble, the speech had markedly improved, and the thickness of the hands and feet had begun to diminish, the tumefactions above the ear and in the supra-clavicular regions were not palpable,

*The preparations used by me were kindly furnished by Dr. Paul Gibier and Dr. George Crary, of this city.

the skin of the palms of the hands and of the feet was distinctly less dry; the scanty hair on the scalp, however, had become still scantier, the reaction of the urine was still alkaline, of rather low specific gravity, and contained rather a large amount of phosphates.

Fig 2.—Twenty-first Day of Treatment.

The patient expressed a feeling of great comfort, and moreover a sensation of general warmth which she had not felt for years, and which had been developed at the very beginning of treatment. The raw gland had, however, become very distasteful, and she could be persuaded only with difficulty to take it.

On January 7th, after twenty-three days of its use, its ingestion was followed by vomiting and a rather acute disturbance of digestion, and the treatment was discontinued for ten days. The improvement in the patient's condition was, however, uninterrupted during this period.

It was noted that the temperature curve rapidly lost its irregularity on the temporary discontinuance of the treatment, and became normal, and the pulse gradually fell to 76–80.

On January 16th, five weeks after the first ingestion of the raw gland, the following note was made:

The patient is hardly recognizable as the one of a month ago. The myxœdematous signs, as far as the face is concerned, have entirely disappeared. The expression is natural, there is no longer any appreciable swelling or increased thickness of the skin of the face, neck, or trunk, of the lips or tongue. The speech has lost its peculiar characteristics. The hearing has so much improved that the patient now hears the ordinary conversational voice across the ward, and also the singing in the chapel of the hospital, one hundred and fifty feet distant. The dryness of the skin has markedly diminished, and beginning desquamation on the hands, feet, and scalp is noticeable. The hands have recovered their normal size, and the feet are markedly thinner. An abundant new growth of fine hair on the scalp and eyebrows is appreciable. With the disappearance of the tulness of the neck, a satisfactory examination is possible. The thyroid gland is not appreciable.

On January 19th the treatment was again initiated, and has been continued to the present date. A slight change has been made in its technique and in the dosage. The expressed juice of the gland rather than the raw substance has been given, as the former is without taste when administered in milk or water, and does not produce any digestive disturbance. Fifteen minims of the juice, representing one-quarter of an average amount obtained from one lobe of the gland of the sheep, has been given once weekly, by the mouth, in a little milk. The improvement has been continuous (Fig. 3).

During the first week in February desquamation of the skin of the entire body occurred; very large strips, several inches in length and breadth, could be easily removed from the different areas. The process was very rapidly completed, leaving a delicate, elastic, normally moist skin and of a natural color. The entire scalp became thickly covered with a new growth of hair, and the same was true of the eyebrows. A new growth about the pubes was also noticeable. During the early period of the treatment the hair of the scalp which still remained rapidly fell out.

The patient became cheerful, bright, and the improvement in the mental processes was very marked. Gradually the patient became able to sit up without support, and then to stand, and finally to walk. It will be recalled that on admission she had practically been bedridden for a year.

A study of the photographs taken before treatment and at subsequent intervals illustrates the marvellous change which has been effected in the patient's appearance and condition.

The similar clinical observations which have now been made by many careful investigators have secured for the method of treatment which I have described not only a very general recognition, but they naturally have suggested therapeutic possibilities which hitherto have hardly been dreamed of. The field of study and investigation

Fig. 3.—Eighteen Weeks after Treatment.

thus opened is a wide and most interesting one. The future history of the cases of myxœdema and sporadic cretinism, which are reported in the present paper, will be watched with interest.

Present indications suggest the possibility that the maintenance of the extraordinary improvement noted may be secured only by the indefinite continuance of the treatment.

TABLE I.—*Cases of Thyroid Grafting.*

Reporter	Sex and age.	Previous condition.	Method.	Results.	Reference.
Kocher	Not stated		Implantation of small portions of goitrous gland.	Speedy absorption	Brit. Med. Jour., July 26, 1890, p. 201.
Kocher	Two cases		One-half gland grafted into abdominal wall.	Aseptically exfoliated.	Brit. Med. Jour., July 26, 1890, p. 201.
Kocher	Three cases.		Whole gland inserted loose into abdominal cavity.	One case greatly improved.	Brit. Med. Jour., July 26, 1890, p. 201.
Bircher	Female, 33	Epileptiform seizures after accidental total extirpation of thyroid.	Intra-peritoneal graft of portions of apparently normal human thyroid.	Cure: relapse after three months. Fresh grafting; nine months later second relapse.	Volkmann's Samml. klin. Vorträge, No. 357, March 5, 1890.
Lannelongue and Legroux	Female, 14	Cretin; idiotic; thyroid apparently absent.	Two-thirds of one lobe of sheep's thyroid inserted into right submammary region.	Result not reported	Soc. de Biol., March 8, 1890.
Bettancourt and Serrano	Female, 36	Myxœdema for several years; no thyroid perceptible.	One-half sheep's gland inserted into each submammary region.	Immediate and marked improvement in physical condition; mental condition not stated.	La Semaine Méd., Aug. 13, 1890, p. 294.
Merklen	Female, 41	Myxœdema for ten years; mental condition fair; metrorrhagia.	One lobe of sheep's thyroid inserted into submammary region.	Cessation of metrorrhagia: improvement of myxœdema.	Mercredi Méd., Nov. 19, 1890, p. 571.
Macpherson	Female, 39	Myxœdema for three years; melancholia, stupor, delusions of fear.	Portions of sheep's gland inserted into each submammary region.	Cured	Edin. Med. Jour., May, 1892.
Robin	Male, 7	Congenital myxœdema	Two lobes from sheep inserted into submammary region.	Had previously been treated successfully by injections of thyroid juice: grafting done to perpetuate effect.	Lyon Méd., Aug. 7, 1892.
Gibson	Male, 6	Sporadic cretinism	Two lobes from sheep inserted into pectoral region; ten months later, two lobes inserted into abdominal cavity.	Very marked improvement after first operation; myxœdema cured; cretinism lessened.	Brit. Med. Jour., 1893, vol. i., p. 58.
Affleck	One case	Sporadic cretinism	Grafts into mammary regions	Very much benefited	Lond. Med. Press, Feb. 22, 1893, p. 200.

TABLE II.—*Cases Treated by Injections.*

Reporter.	Sex and age.	Duration of disease.	Method.	Duration of treatment.	Results.	Remarks.	Reference.
G. R. Murray	Female, 46	Four to five years	Glycerine extract of one-half sheep's gland twice per week.	Three months.	Very much improved	Relapses when treatment is discontinued.	Brit. Med. Jour., Oct. 10, 1891, p. 746; Aug. 27, 1892, p. 449.
G. R. Murray	Female, 52	Twelve years	Glycerine extract of one-half sheep's gland once per week for four months; each second week for three months.	Seven months.	Improved very considerably.		Brit. Med. Jour., Aug. 27, 1892, p. 450.
G. R. Murray	Female, 62	Six to seven years.	Glycerine extract of one-half sheep's gland each week.		Very marked improvement.	Sudden death from heart failure after exertion.	Brit. Med. Jour., Aug. 27, 1892, p. 450.
G. R. Murray	Female, 64	Five years	Glycerine extract of one-fourth to one-half sheep's gland each week.	Three months.	Considerable improvement.	Death from sudden heart failure.	Brit. Med. Jour., Aug. 27, 1892, p. 450.
A. T. Davies	Male, 43	Thirteen years	Murray's method	About seven months.	Remarkable improvement.	Relapses when treatment is discontinued.	Brit. Med. Jour., Aug. 27, 1892, p. 450.
A. T. Davies	Not stated	Not stated	Murray's method	Not stated	Gradual improvement.		Brit. Med. Jour., Aug. 27, 1892, p. 451.
Cecil F. Beadles	Female, 50	Eight years	Injections at various intervals, in all nineteen.	Five months	Insanity cured; physical symptoms practically cured.	Form of insanity: delusions and religious melancholia.	Brit. Med. Jour., Dec. 24, 1892, p. 1386.
Hearn	Three cases.	No details			Improved very much		Brit. Med. Jour., Aug. 27, 1892, p. 452.
Ernest C. Carter	Female, 43	More than five years.	Murray's method	Three and one-half months.	Insanity improved; physical symptoms cured.	Form of insanity: melancholia with paroxysmal excitement.	Brit. Med. Jour., April 16, 1892, p. 805.
Wallace Beatty	Female, 45	Five to six years	Murray's method	Two months	Practically cured		Brit. Med. Jour., March 12, 1892, p. 544.
Mendel	Female, 58	Eleven years	Injections daily	One month	Much better physically and mentally	Marked mental apathy	Deut. med. Woch., Jan. 13, 1893.
Napier	Female, 54	Five years	Injections at various intervals, sixteen in all.	Six weeks	Much improved		Glasgow Med. Jour., Sept., 1892, p. 161.
Claye-Shaw	Female, 33	Four years	Injections of thyroid juice.	Three months.	Quite well in all respects: insanity cured.	Form of insanity: restless melancholia, almost homicidal.	Brit. Med. Jour., Aug. 27, 1892, p. 451.
Mitchell-Clark	Male, 48	Not stated	Murray's method	Two months	No result		Brit. Med. Jour., Aug. 27, 1892, p. 451.
Mitchell-Clark	Middle age.	Not stated	Murray's method	Six weeks	No result		Brit. Med. Jour., Aug. 27, 1892, p. 451.
Robin	Male, 7	Congenital	Daily injections of thyroid juice.	Not stated	All traces of œdema disappeared: other symptoms improved.	Grafting done subsequently to perpetuate effect.	Lyon Méd., Aug. 7, 1892.
Henry	Female, 44	Fourteen years	Injections bi-weekly for ten weeks; weekly for eight weeks.	Eighteen weeks.	Vastly improved	Subsequently treated by thyroid feeding.	Brit. Med. Jour., April 8, 1893, p. 737.
Hurry Fenwick	Three cases.				Improvement	No details given	Brit. Med. Jour., Oct. 22, 1892, p. 894.
Ruffer	Two cases				Apparently cured	No details	Brit. Med. Jour., Oct. 22, 1892, p. 894.
Hadden	Two cases				Not stated	No details	Brit. Med. Jour., Oct. 22, 1892, p. 894.
Bouchard	Two cases				Rapid improvement		Bull. de Méd., Oct. 2, 1892.
Barron	Female, 64	Five years	Two injections per week.	About three months.	"Considers herself well."		Brit. Med. Jour., Dec. 24, 1892, p. 1384.
Barron	Female, 55	Not stated	Two injections per week.	Seven weeks	Very much improved	Under treatment at date of report.	Brit. Med. Jour., Dec. 24, 1892, p. 1384.
Cockbill	Female, 32	Four months	Injections thrice weekly.	Two months (?)	Cured	Thyroid was enlarged instead of atrophied.	Brit. Med. Jour., Jan. 7, 1893, p. 8.
Lundie	Female, 54	Fourteen years	Murray's method	Six weeks	Improved	Treatment discontinued on account of abscesses; subsequently treated by thyroid feeding.	Brit. Med. Jour., Jan. 14, 1893, p. 64.
Wichmann	Female, 35	Two years	Glycerine extract of nine glands in all.	Five weeks	Cured: subsequently relapsed to a slight degree.	Form of insanity: hypochondriasis and melancholia.	Deut. med. Woch., Jan. 14, 1893, and March 16, 1893.
Wichmann	Female, 36	Four years	Injections of glycerine extract.	Two months	Cured: symptoms of slight relapse six weeks later.		Dent. med. Woch., March 16, 1893.

TABLE III.—*Cases of Thyroid Feeding.*

Reporter.	Sex and age.	Duration of disease.	Method.	Duration of treatment.	Results.	Remarks.	Reference.
Mackenzie	Female, 39	Four years	Raw thyroid and glycerine extract.	Three weeks	Marked improvement		Brit. Med. Jour., Oct. 29, 1892, p. 940.
Fox	Female, 49	Not stated	Glycerine extract, and, subsequently, gland lightly cooked.	Three and one-half months.	Cured		Brit. Med. Jour., Oct. 29, 1892.
Bramwell	Female, adult.	Not stated	One-half gland on alternate days at first, and smaller doses subsequently.	Not stated	Very much improved	Produced symptoms of heart failure at first.	Brit. Med. Jour., Feb. 25, 1893, p. 411.
Foulis	Not stated		One-eighth thyroid		Death from violent diarrhea after first dose.		Lond. Med. Press, Feb. 22, 1893, p. 200.
Foulis	Not stated		One-eighth thyroid twice per week.	Eight weeks	Greatly benefited.		Lond. Med. Press, Feb. 22, 1893, p. 200.
Baber	Male, 53	Six years	One gland at irregular intervals; in all, five glands.		Marked improvement.		Brit. Med. Jour., Jan. 7, 1893, p. 10.
Lundie	Female, 54	Sixteen years	One-sixth gland twice per week.		Cured	Previously treated by injections.	Brit. Med. Jour., Jan. 14, 1893, p. 64.
Holman	Female, 44	Seven years			Practically well	Still under treatment	Brit. Med. Jour., Jan. 21, 1893, p. 114.
Davies	Four cases				Improved rapidly	Heart action extremely enfeebled in one case by remedy.	Brit. Med. Jour., Feb. 4, 1893, p. 252.
Calvert	One case		Fried gland		Vastly benefited		Brit. Med. Jour., Feb. 4, 1893, p. 235.
Pasteur	One case				Much benefited		Brit. Med. Jour., Feb. 4, 1883, p. 235.
H. Mackenzie	Female, 40				Practically well		Brit. Med. Jour., March 4, 1893, p. 461.
Hadden	One case		Powdered thyroid extract.	One month	Quite well		Brit. Med. Jour., March 4, 1893, p. 461.
J. H. Benson	Middle age.	Eight years.	Thyroid extract twice daily.	Three months.	Nearly well		Brit. Med. Jour., April 15, 1893, p. 795.
Henry	Female, 44	Fourteen years	One lobe every second day.		Vastly improved	Previously treated successfully by injections.	Brit. Med. Jour., April 8, 1893, p. 737.
Vermehren	Female, 29	Twenty-four years.	Powdered extract		Marked improvement		Deut. med. Woch., March 16, 1893, p. 255.
Laache	Male, 49	One year	Powdered extract	Three and one-half months.	Cured		Deut. med. Woch., March 16, 1893.
Howitz	Female, 42	Seven years	Four lobes from calf daily for one month, and, subsequently, two lobes every second day.		Much improved		Deut. med. Woch., March 16, 1893, p. 255.
Shapland	Female, 52	Ten years	One-half thyroid daily, slightly cooked.	Three months.	Quite well		Brit. Med. Jour., April 8, 1893, p. 738.
Thompson	One case		One-fourth gland once per week.		In seven weeks had grown one and one-fourth inch; general condition much improved.		Lond. Med. Press, Feb. 22, 1893, p. 200.
Thompson	Male, 18		One-fourth gland once per week.		In eight weeks grew one and one-fourth inch.		Lond. Med. Press, Feb. 22, 1893, p. 200.
Bruce	One case				Cured	No details	Lond Med. Press, Feb. 22, 1893, p. 200.
Dunlop	Five cases				One improved, four not stated.		Lond. Med. Press, Feb. 22, 1893, p. 200.
Church	Two cases				Not stated	No details	Lond. Med. Press, Feb. 22, 1893, p. 200.

In conclusion, I shall offer a few suggestions in regard to the technique of the treatment. From my personal experience I believe that the best form in which to administer the gland is the expressed juice given in a little milk or water. Dr. George Crary, of this city, has found the size and weight of the lobes of the sheep to vary so widely that he has been led to adopt a uniform standard for the preparation of the juice, viz., one of which one drachm of the glycerine extract represents grains xxiv. of the gland. At the beginning of treatment in any given case, fifteen minims of this preparation should be given daily, and its effects carefully watched. If no effect is obtained, the dose should be doubled, and still further increased if necessary. As improvement occurs, smaller doses, and given at longer intervals, will be found sufficient to secure further good results, until finally ten or fifteen minims administered no oftener than once a week, or even at longer periods, will be indicated. During the first weeks of treatment, experience suggests the wisdom of carefully guarding against ill effects, such as symptoms of heart failure, etc., by insisting upon the avoidance of all physical exertion on the part of the patient.

Some Spelling Reforms.—After four years of careful investigation and great labor the American Association for the Advancement of Science has adopted a set of rules for the spelling and pronunciation of chemic terms. Among these rules are those advocating the dropping of the final *e* in all such words as *bromid*, *iodid*, *chlorid*, and the like, and also in all such as *bromin*, *iodin*, *chlorin*, etc. Is there any reason, earthly or unearthly, for not following the suggestion? Why shall we not drop the conjoined letter diphthongs in all words? Let us spell all our words from the Greek *αἶμα*, with the single vowel *e* instead of *æ*. Let us say *hemorrhage*, *hemostatic*, etc., clear through the list. The same with all other *a's*, usually spelled *æ*, as in *orthopedic*, *pediatric*, *anesthetic*. The same with *œ*: Let us accept *edema*, *celiotomy*, *diarrhea*, *fetus*, etc.—*Dr. G. M. Gould.*

THE OPERATIVE TREATMENT OF UTERINE PROLAPSE OR SACRO-PUBIC HERNIA.

By F. BYRON ROBINSON, B.S., M.D.,

PROFESSOR OF GYNECOLOGY IN CHICAGO POST-GRADUATE SCHOOL; GYNECOLOGIST TO WOMAN'S HOSPITAL, TO CHARITY HOSPITAL, TO COLUMBIA DISPENSARY, AND TO POST-GRADUATE HOSPITAL.

The causes of uterine prolapse, or sacro-pubic hernia, are still imperfectly known. Imperfect knowledge of causes is sure to be surrounded with deficient knowledge of effects. The deficient knowledge of the various causes at work producing sacro-pubic hernia has induced various operators to invent and practise different kinds of operations for the cure or relief of this common disease in women. This article is not to deal with the etiology of sacro pubic hernia, but every one of the three great cases inducing it must be borne in mind, viz.: *a*, Intra-abdominal pressure; *b*, deficient support in the sacral segment of the pelvic floor; and *c*, loss of tone in the anterior pelvic segment. Any operation which will cure sacro pubic hernia must remove or overcome the forms under *a*, *b*, and *c*. Opinions vary very much to-day both as to etiology of prolapse and its methods of cure. In sacro-pubic hernia the essential organ first involved is the vagina, hence narrowing that will not alone produce a cure and keep the uterus in place. One writer takes the ground that the uterus itself has nothing to do with prolapse, so that it will be seen that there is left only the floor of the pelvis to repair in order to cure sacro-pubic hernia. Simon, of Heidelberg, was probably the first gynecologist who had systematic success in operations for sacro-pubic hernia. He freshened portions of the vaginal outlet and united the denuded surface. Time fled on and men saw that the vagina had an anterior and posterior column which was very valuable to aid in operative procedures to relieve sacro-pubic hernia. So these columns were spared in the denudation. The columns of the vagina are the remnants of Müller's ducts where they coalesce to form the vagina. Some, as Neugebauer, thought that to unite a denuded surface of the anterior to the posterior vaginal wall would prevent the uterus being forced out. But subsequent births rupture this bridge of union; then follows Emmet's and Martin's operations, which are just alike in principle. They denuded lateral portions of the vagina and united the surfaces. They thus narrowed the lower third of the vagina and stiffened the pelvic floor. Better, they attempted to restore the direction of the vaginal canal, just as we must do in the radical cure of inguinal hernia. If success follows operation for inguinal hernia we must restore the obliquity of the inguinal canal by lifting the cord high up to the original site of the internal inguinal ring, and uniting the peritoneum internal to it. As the uterus rests in the floor of the pelvis it cannot prolapse unless it mounts over the perineum.

Now, just as soon as the vaginal canal loses its obliquity, or, in other words, becomes straight, and the upper end of the vaginal tube approaches the lower end of the vaginal tube, sacro-pubic hernia will follow. The uterus and vagina will be forced out. One of the great progressive forces in sacro-pubic hernia is the pointed shape of the cervix, which bobs backward and forward at every breath through the vaginal outlet. The cervix is a veritable drill, which, like an advancing wedge, gradually widens the vaginal outlet, and there is no hope for cure until the cervix is forced in some other direction. The point of the cervix can be destroyed only by amputating it so that only a broad stump end is left. A small little polypus will soon cause uterine prolapse, because it drags on the cervix, and soon gets the cervix pointed in the direction of the vaginal canal. Then all the pointed cervix has to do is to dilate the vagina, which it does at every step, breath, song, or cough. The cervix can be forced in a backward direction by denuding a portion of the anterior vaginal wall and uniting the edges. We have now the three operative procedures which will really cure sacro-pubic hernia, viz.: *a*, Stiffen the pelvic floor; *b*, amputate the cervix, and *c*, direct the cervix backward by narrowing the anterior vaginal wall. All three are not needed at every operation, but the judgment of the operator must decide in each case. No operator can successfully cure sacro-pubic hernia by trying all published operative procedures, but he must rather select what he sees to be the most reasonable and safe, and then follow it persistently. The writer is no friend to pessaries, and believes in curing prolapse by operation, and the above three operations will be about as successful as any. It will be rare to employ the three parts in any one case.

1. The cervix should be first amputated, if it is required. It will be of course amputated in every case of elongation. The amputation will leave a wide (non-pointed) cervix, so shortened that it will not induce the vagina to gradually widen at each uterine movement, which occurs at every breath, or step, or increase in abdominal pressure. Silk, chromicized catgut, or silkworm-gut may be used for suture.

2. The second step is to denude a part of the vagina just ahead of the cervix—say an oval surface as large or larger than a silver dollar—and unite its edges with sutures. This procedure accomplishes two objects, namely, *a*, it narrows the vaginal lumen and aids in lifting the bladder up. *b*, It directs the cervix backward toward the sacrum.

3. The third part of the operation is the most important, and that is to strengthen or stiffen the pelvic floor. For the past two years I have used Tait's "flap," and I am fully satisfied that I can do better with it than with any other method. I have in later work with the flap modified the method of incision. The modification consists in making deeper cuts in every direction and exposing wider areas of tissue. Now, deep anterior and deep posterior clips are made with the scissors, and results are better. I now separate the rectum and vagina from one to two inches, which gives very long flaps. From four to eight silkworm-gut sutures are used in uniting the wound. While a pupil of Mr. Tait I was surprised to see him only use three or four sutures in such large perineal wounds. My experience is to use six to eight, and insert them very deep in the exposed tissue, so as to bring a large amount of tissue in the middle line, so that the floor of the pelvis will be restored, so that the uterus will rest on the pelvic floor at right angles to the direction of the vaginal lumen. I use no dressings of any kind, and do not allow the perineal wound to be irrigated unless urine or fæces run over it. A small rubber tube should be introduced into the rectum, so that the gas will escape easily. In one of my cases accumulation of gas and its penetration through the recto-vaginal septum between sutures caused a recto-vaginal fistula. One thing should be insisted on, and that is, to leave the sutures in for at least three to six weeks. My observation in experiments on dogs convinced me that wounds do not unite strongly under three weeks, and they are very much stronger united in six weeks. I do not like to remove the sutures in a case of Tait's flap for a month to six weeks. Salts or oil is administered on the fourth day, and several times a day an enema is given. Early in doing Tait's flap for sacro-pubic hernia I did not make sufficiently extensive flaps, and in one case of prolapse it returned in ten months. Later results with Tait's flap, and denudation of anterior vaginal wall and amputation of cervix, gives excellent results. Repeated trials with Tait's flap and the other one or both procedures has convinced me that sacro-pubic hernia can be radically cured, and that pessaries should be abandoned in any case which offers no obstacle to operation, such as old age, debility, etc. Pessaries must be gradually increased in size to suit a case.

Conclusions. — 1. Sacro-pubic hernia is best cured by using from one to three operations at the same sitting.

2. If required, the cervix should be amputated, to destroy its pointed extremity, which acts as a wedge to open the vaginal canal.

3. A portion of the anterior vaginal wall should be denuded and its edges united. The object of this is to force and direct the cervix toward the sacrum and narrow the upper half of the vaginal wall, also to elevate the bladder

4. The third step is to stiffen the pelvic floor—to restore the pelvic floor and also the obliquity of the vaginal canal. So far I have had the best results by the use of Tait's flap operation for this purpose. The front and back cuts should always be employed in sacro-pubic hernia.

5. The sutures should not be removed before four to six weeks. The patient should remain in bed at least three weeks. Wounds do not heal very strongly before four weeks and are much stronger after six weeks. No dressings or vaginal irrigations should be used. The legs should be tied firmly together. It may be observed in this operation that the direction of the vaginal lumen and the cervix must be as much at right angles as possible to insure final success; in short, to imitate original nature.

ON THE TREATMENT OF SEMINAL INCONTINENCE.

By L. HARRISON METTLER, A.M., M.D.,
CHICAGO, ILL.

THE cure of few troubles affords more complete satisfaction to both patient and physician than that of seminal incontinence. A persistent effort is demanded of the latter, and a sincere desire for relief is necessary in the former. A man's virility is usually of such transcending importance to himself, and the imaginations of most men are so wrought upon by the disastrous results of spermatorrhœa portrayed in the clap-trap literature of special nostrum venders, that one's depth of despair is only equalled by the intense gratitude for the relief obtained. Seminal incontinence is too often injudiciously or indifferently treated. In the first place, it should never be forgotten that the seminal loss is not a disease, but a symptom of a number of possible defects having other symptoms as well. In the second place, as a kind of corollary to the former statement, it should be remembered that no two cases can ever be treated exactly alike. The variety of its causes, the differences in its character, and the peculiarities of the patients afflicted, presuppose for it a varied therapy.

No one will deny that seminal incontinence is essentially a motor neurosis. Ah! that happy word neurosis. What a poverty of knowledge it conceals! what a wealth of ignorance it reveals! When at last we are driven to cover, how safe one feels to call an unknown and unexplained disease a neurosis. What is a neurosis? So far as I can comprehend, it seems to signify an abnormal expression of nerve-force, an unaccountable activity in the function of nerve centres. Apparently this activity may be more or less than what obtains in health, but it seems always to be in the line of the normal function. But why are not all nervous affections, organic as well as functional, neuroses? A diseased sensory centre, for instance, never reveals motor symptoms, though every kind of organic lesion may disturb more or less the normal function of that same centre. To call a disease a neurosis is to confess that it has an organic cause of which we are still ignorant. The origin of the neuroses is usually reflex, and insanity from a mental shock is as much a neurosis as headache from an eye strain. As our knowledge of pathology increases, the list of so-called neuroses will proportionately diminish. It would be fortunate for medicine if our knowledge of the physical bases of all troubles were sufficiently exact to enable us to abolish entirely so vague and inconsistent an expression as a "functional disease."

The causes of seminal incontinence are readily discovered if the patient is candid in his admissions and the physician searching in his examination. Patients most frequently exaggerate their trouble. It is physiological for an adult to lose a certain amount of semen three or four times a month. Usually this happens at night, as the result of an erotic dream, and is accompanied with an erection. We have all seen cases unnecessarily alarmed at this, and it is always a pleasant duty to allay the fears of such individuals. With men of robust constitutions the loss of semen every few days is physiological rather than otherwise. The same is true of those who lead continent lives, or suddenly cease a course of excessive sexual indulgence.

Of all the causes of seminal incontinence, overstimulation is the most common. Masturbation, excessive sexual intercourse, reading of lewd literature, filling the mind with sensual images, are some of the more ordinary means of overstimulation. One of my patients was a young Englishman who had been taking a cold spinal douche every morning. The cessation of this habit put an end to the spermatorrhœa. Masturbation is a cause often overlooked, for the reason that the patient denies the practice. It is not unwise to suspect this cause before all others, as it is by far the most common. A young man was recently brought to me by his mother because he was not seemingly improving under the care of his former physician. He was a bright and intelligent college lad, about eighteen years of age. He was sallow in appearance and extremely irritable in disposition. His pulse beat regularly, 130 to the minute, as I found after keeping him quiet a long time in my office. Having several weeks before undergone tonsillotomy, he said his physician attributed his condition to general debility, and prescribed a tonic and throat anodyne. Asking the mother to step out of the room, I charged the young man with masturbation. After a moment's surprise and hesitation, he freely admitted the fact, and declared he was so ashamed of the habit that he had never told anybody of it before. His further confession showed that he had been a confirmed masturbator for a number of years, and that he had nocturnal emissions without erections. In such cases I find that the only way to secure a confession is to charge the patient with the fact, as though it were self-evident and concealment quite impossible. I have noticed that a frequent course of seminal incontinence is the ingestion of large draughts of fluid just before retiring, together with the habit of sleeping upon the back beneath warm covers. I recall one of many instances of this that came to me in great alarm. The discharge was slight, and a mild tonic with the regulation of the patient's sleeping habits resulted in a cure. I have seen an enlarged prostate, a stricture, an elongated prepuce, hæmorrhoids, and constipation, all give rise to seminal incontinence. When advanced in years, many men attribute the discharge to their age, with its attendant weakness and the diminution of sexual intercourse. In these cases an opinion ought never to be given without an examination of the prostate gland. Prostatorrhœa is not infrequently associated with seminal incontinence, especially as the posterior urethra is more or less inflamed and irritated near the openings of the ejaculatory ducts. Vesical calculi, fissure of the anus, and ascarides should always be remembered as possible causes. Any lesion that awakens an undue excitability of the genito-urinary centre in the lumbar cord, such as trauma, incipient ataxia, local meningitis, or hemorrhage, may be the origin of the trouble. Cerebral weakness and psychic influences that remove the inhibitory control of the mind, such as senile dementia and insanity of various forms, may produce it. Many instances of psychopathia sexualis, cited by Krafft Ebing, were troubled with unnatural seminal losses, and the possibility of some similar cause should always be remembered in every case not otherwise explainable. In these as well as in other weakened states of the system, the mere presence of the opposite sex, amatory conversation, shampooing of the head, and the exhibition of a female fetich, are all capable of producing an involuntary emission. It requires much shrewdness to discover the neuropathic trouble underlying these simple exciting causes, for the patient is ofttimes ashamed of his unusual sensi-

bility, and strives hard to conceal it. It is these neuropathic cases that become so hypochondriacal and need the most encouragement. With them the disease is the result of the nervous disturbance rather than *vice versa*.

It seems to me quite needless to subdivide seminal incontinence into different varieties, as some writers have done. These subdivisions represent merely different degrees of the same trouble. The nocturnal is not essentially different from the diurnal variety, though it is apt to be more severe. The momentary environment of the patient obviously modifies the severity of the discharge, but that is no direct evidence of the severity of the disease. Each case must be studied in its entirety, and its symptoms taken *en masse*, before a candid opinion can be given in regard to its prognosis. The only practical subdivision is into seminal incontinence, spermatorrhœa, and impotence, since one or all may be present in the same case. The semen consists of the products of several glands, and its loss is not indicative of so profound a disturbance as spermatorrhœa, though spermatozoids are always found more or less in it. Spermatorrhœa is a serious affection, and consists of the frequent discharge of the products of the testicles along with the semen. Sometimes the spermatic fluid is voided several times a day, especially with the acts of micturition and defecation. Impotence, or the absence of the power of erection, may be the result or mere accompaniment of seminal incontinence. It is usually associated with a profound degree of functional disturbance of the genital apparatus, and the fear of becoming impotent is the most frequent source of alarm among those affected with spermatorrhœa. Aspermatism, however, is sometimes present when the power of erection is altogether perfect. Certain general symptoms point to spermatorrhœa. It may be surmised when the patient complains of great weakness, headache, dizziness, troublesome dreams, occasional chilliness, extreme restlessness, general irritability, inaptitude for business, difficulty of concentrating the attention, palpitation of the heart, heavy breathing, an unnatural distaste for society, and a marked depression of spirits; in a word, all the subjective symptoms of a severe neurasthenia. In addition to his feelings, the patient will show an outward irritability and restlessness, his physique is wan and wasted, his skin is not clear, but tawny and dark, his gaze is unsteady and "sheepish;" he is easily startled by a sudden noise; the pulsations of his heart are excessively rapid, and his countenance portrays distress and anxiety. He is subject to continuous slight tremors; he is irregular in his gait; and he assumes the manner and attitude of a hypochondriac. Such a picture would at once justify a suspicion of spermatorrhœa. Should the patient now admit the fact, his attendant may tell him that, as his trouble progresses, his mind will become enfeebled, his memory for names and places will weaken, his physical strength will continue to diminish, his muscular tissues will grow flabby, his appetite will become capricious, his eyesight dull, and his hearing annoyed with constant tinnitus, his headaches will be more severe, his nerves will lose their steadiness, his nights will be wakeful, and his whole being, both physical and mental, will become a complete wreck. As the moral treatment is so important in this trouble, we are justified in painting the ultimate result of the disease as black as possible. We should tell the patient that he runs the chance of losing his virility, that the spermatozoa will finally disappear entirely from his semen, while the latter will flow continuously from him; that he may become completely impotent, and that the consummation of marriage will be for him a thing totally impossible. If he be a masturbator, the lesson may be still further impressed by referring to the large number of cases of epilepsy and insanity attributed to this vile practice.

In marked contrast to this dark outlook, we may assure the patient that with persistent, well-directed effort, no case of spermatorrhœa can fail to recover to a large extent, and that nearly all can be restored to a condition of almost perfect health. Having thus plainly addressed the patient, especially if he be a young man, upon the fearful results of the disease if permitted to go unchecked, and at the same time encouraged him with the hope of a complete cure, we have already accomplished more than half of that hopeful result. I know there are medical men who say these cases are beyond redemption, and that they have not the will-power to persist in the treatment or to resist the baleful practices that originally brought them to their present state. I am persuaded that this is not true of the majority, for I find that most of them are sincere and determined in their desire to get well, and need only the proper assistance to enable them to do so.

First and foremost in the treatment of seminal incontinence, I place moral and hygienic means. Masturbators who cannot be wholesomely frightened with the ultimate results of their evil practices, are indeed hopeless cases. In every instance the cause must be discovered before any satisfactory progress can be anticipated. It would be absolutely useless to attempt moral or hygienic measures if the trouble were dependent upon an incipient ataxia, dementia paralytica, enlarged prostate, or stricture. A most exhaustive examination must be made for every possible reflex cause, and it must be removed before everything. Where these reflex causes are absent or have been entirely overcome, my chief reliance is upon the use of the bath, proper rest and exercise, the passage of the sound, and the administration of atropia and the bromides. I know of nothing so effective as these measures to conquer an obstinate seminal incontinence.

The patient should be instructed to avoid every kind of stimulus and over-fatigue. Anything that is likely to irritate the genital organs, such as tight clothing, bicycle and horseback riding, should be refrained from. His food should be of the blandest and most nutritious sort. Tea, coffee, alcohol, and tobacco must be abandoned for a time. He must take a light dry diet, and abstain from drinking large quantities of fluid before retiring at night. It would be a good plan for him to set the alarm-clock to awaken him a couple of times in the night to empty his bladder. He must sleep in a cool, well-ventilated room, with as little bed-clothing on him as possible. He should always occupy a bed alone, and cultivate the habit of lying upon his right side. It might be well to have the head of his bed turned toward the north, for there may be something in the notion that one sleeps better when the electric currents of the body and earth are parallel. A warm bath before retiring is soothing and tonic, while a rapid sponging of the whole person with cold water in the morning lends vigor for the day. Of course, all literature and pictures of a sensual nature must be rigidly eschewed; and to keep the thoughts pure and healthful, it would be well for the patient to acquire a hobby to which he could turn for amusement in his leisure moments.

In all cases of seminal incontinence there is more or less inflammation of the prostatic urethra and irritability of the whole canal. If this be severe the patient will describe a kind of burning, sore sensation at the end of the penis, and he will complain of the frequency with which he has to pass his water on account of the uncomfortable sensation of an over-distended bladder. If these inflammatory symptoms are at all pronounced, hot sitz-baths, soothing oleaginous injections, and the free use of cathartics would be advisable. Leeches or blisters to the perineum are necessary at times. I am convinced there is no better treatment for the irritability of the posterior urethra, after the more acute symptoms have subsided, than the frequent passage of the sound. At first this should be done at intervals only of two or three days, the instrument being retained for two or three minutes. Later on it should be introduced daily, and held in the urethra for fifteen or twenty minutes. In inexperienced hands a small soft sound or catheter should be first employed, and larger ones used as the mucous membrane becomes more tolerant. Better, however, than the soft

instruments are the steel sounds, when carefully introduced, since they are less painful to pass and are more vigorous in their therapeutic action. The resisting contact of a solid body against the mucous membrane of the urethra greatly lessens its sensibility, while the gradual increase of the size of the instrument as the treatment proceeds, helps to relieve the congested blood-vessels. If there be any strictures present, as there are apt to be in all old cases, these, as well as the exudative thickening of the urethral membrane, are more or less reduced. I wish to recommend most emphatically the use of the bougie in the treatment of seminal incontinence. If there be any pronounced impotence of a neurotic origin, the passage of the feeblest possible electric current through the steel sound while it is *in situ* will in some cases prove beneficial, but only the mildest currents should be employed. This, however, as well as Trousseau's rectal pessary, at one time so popular, will rarely if ever be needed, since other means are quite as effective.

Without the measures already recommended, the use of drugs alone will surely end in failure. It is astonishing how few of the many medicaments suggested for this trouble are really efficacious. Lupuline, cimicifuga, ergot, camphor, conium, and similar remedies have seemed to me to afford only a temporary relief, if any at all. Atropia, the bromides, and strychnia are the medicines I place most confidence in. Of these, atropia stands by all odds at the head. By checking the activity of the seminal glands the alkaloid of belladonna enables them to recover their wonted tone and function. A pill containing gr. $\frac{1}{80}$ or gr. $\frac{1}{50}$ of atropia should be administered every night at bedtime, so that the patient may sleep through the unpleasant sensations which this drug sometimes gives rise to. So satisfactory have I found the use of atropia in this way that I would rather discard every other medicine than it. Sometimes it is well to exhibit, together with the night pill, another in the morning containing a smaller quantity of the drug, say gr. $\frac{1}{200}$ to gr. $\frac{1}{100}$. While employing this remedy the attendant must, of course, closely watch the state of the pupils as a guide to the quantity being ingested. The bromides are frequently effective, but they must be given in massive doses. The potassium bromide may be administered in drachm or drachm and a half doses at bedtime, and diminished upon the first indications of bromism. This salt alkalinizes the urine and blunts the reflex irritability of the spinal cord. At times the other bromides are admirably borne. Some patients, especially the neurasthenic ones, tolerate the mono-bromide of camphor in five- or ten-grain doses. I have no experience to confirm the high recommendation by Hecquet of ferric bromide in three- and five-grain doses. In anæmic cases this would doubtless be a most eligible form in which to administer the bromide. Antipyrin, cocaine, tincture of hops, and dulcamara are all anaphrodisiacs, more or less valuable in neurotic cases. Ergot has been highly lauded in the relaxed condition of the genital organs associated with a continuous discharge. I have not seen the permanent good results, however, that have been claimed for it. Where there is a deficiency in the nervous tone I find the strychnia meets the demand most completely. This powerful spinal cord stimulant should not be considered until all the signs of inflammation and irritability have been removed, and the patient's general physique indicates a return to its former vigor. In doses of gr. $\frac{1}{60}$ to gr. $\frac{1}{30}$ it then acts most happily in restoring the normal functions of the genital glands. Of course the use of iron, especially the tincture of the chloride, arsenic, cod-liver oil, and corresponding systemic tonics, will commend themselves in properly selected cases. The patient's general health must be built up in every way so that a strong constitutional background may be afforded for the improvement of the genital functions. Electricity is a valuable agent in this connection, especially when applied in the manner of general faradization and central galvanization with mild currents.

I have never found it necessary to use other local means of treatment than the bougie; hence I will say nothing of the various injections proposed containing nitrate of silver, tannin, hydrastis, etc. Such injections ought always to be used with the greatest caution, as strictures, impotence, and even death have been caused by them when too strong. They are not only troublesome to carry out perfectly, but I believe are less effective than the earnest, persistent use of the sound. I am assured that with patience and perseverance few cases of seminal incontinence can resist the combination of moral, hygienic, instrumental, and medicinal measures outlined above.

COLUMBUS MEMORIAL BUILDING.

Clinical Department.

GENERAL ANÆSTHESIA.

BY HAZLE PADGETT, M.D.,

COLUMBIA, TENN.

SAM P—— (colored), forty-two years of age, day laborer. Family history negative. Previous to last February never had any sickness, and at that time he began to complain of an uneasy (pain) feeling about both ankles, and this pain gradually extended up both legs, and he then felt it along the upper part of the crests of the tibiæ and slightly around knee-joint. No pains anywhere else. The thing that attracted his attention was a little inco-ordination in walking, which he attributed to rheumatism, just supposition on part of patient, as no physician had ever seen him till I saw him several months after onset of his trouble. When I saw him, about May 1, 1893, I found him up and able with the aid of a stick to walk around the room. No pains in any part of body. All joints in a healthy state. In examining his sensations I found that he had a general anæsthesia of the cutaneous surfaces, could not feel the pricking or sticking of any sharp instrument except in a very few isolated spots, and only then when firm pressure was made; and it was impossible for him to locate place of contact. His sense of pressure was very deficient. The mucous membrane of mouth was anæsthetic, so he could not tell what he was eating, nor could he feel the prick of a needle. The nasal mucous membrane was also in an anæsthetic state, so that tickling the nose was not noticed by patient, and even the conjunctivæ were so anæsthetic that touching and rubbing them with the end of a finger did not elicit any manifestation of feeling. Had incontinence of urine, and when his bladder became filled had no desire to micturate. No sensual desire, penis and testicles anæsthetic. No control over bowels when the desire to defecate came, and many times no such desire ever came. All reflexes, except iris, were markedly increased, and, in fact, ankle clonus so much so that you could almost get paradoxical contraction. Pupils responded to light very slowly, and when I first saw him left pupil was a little larger than right, but that soon passed away. There was no paralysis of any muscle or group of muscles, and eyesight was good. Heart and lungs normal. Abdominal viscera normal. No albumin or tube casts in urine. No fever at any time since I've seen patient. Cerebration is perfect. Patient has never been confined to bed, sleeps well, good appetite, and no trophic changes anywhere. The diagnosis of this case is easy, but the question of its exact etiology is very interesting. You are familiar with the methods of investigating nervous diseases. This patient has a general anæsthesia. Where is the lesion? You know that a wide-spread peripheral neuritis will produce a general anæsthesia, but this patient has no neuritis. Also a wide-spread degeneration of brain cortex, but his cerebration is perfect in every respect and there are no hysterical symptoms. A lesion in the posterior third of the internal capsules of both hemispheres will produce an organic general anæsthesia, and here is the place, in my mind, where the lesion producing this general anæsthesia is situated. Theoreti-

cally a spinal general organic anæsthesia is possible, but in order for it to involve the face the lesion must be in the medulla oblongata, and here you would have involvement of vital centres, and, as was stated, patient has no abnormal action of heart or lungs. The exact cause of this trouble is unknown to me.

THE ABORTIVE OR NUTSHELL TREATMENT OF DIPHTHERIA.

By JOHN T. DE MUND, M.D.,

RIDGEWOOD, N. J.

More than three decades of experience and close observation enables the writer to substantiate these subsequent and most satisfactory conclusions. The simplicity of a thing is often as beautiful as the conception thereof. So we take sulphur and "sulphize" the patient and all contiguous contagiousness. The local or topical application of sulphur, by dusting it upon the diseased part every half-hour, or hour, day and night; also a suspension of sulphur in water, to be used as a gargle as frequently, is of paramount importance. Spraying the throat is of no account. In infants and small children that cannot gargle, dust the part freely and often with sulphur. The burning of sulphur upon live coals, every six hours, in the room or rooms, should not be neglected. So much for the local or topical medicament.

For internal use, adult (proportion the dose for children and infants) give the following:

R.	Tr. ferri chlor.	ʒ ss.
	Spts. minderus	ʒ iss.
	Glycerine	ʒ j.
	Tr. aconitia	♏ ss.
	Aq. font q. s. ad	ʒ viij.

M. Sig.: Shake well. Teaspoonful every half hour for several doses, then every hour or two, day and night.

A relay of nurses is an absolute necessity. Iced milk and lime-water, twelve to one, *ad libitum*. Brandy as the case necessitates. Last and not least, and not to be forgotten, a large dose of hydrarg. chl. mite., preceding all other internal administration.

By this method the onus is simplified, the nidus is destroyed, and the lesion is jugulated.

THE USE OF HYDROGEN DIOXIDE IN THE PERITONEAL CAVITY.

By FREDERICK H. WIGGIN, M.D.,

NEW YORK.

In a paper entitled "Intestinal Obstruction, Diagnosis and Treatment," which was read at the centennial meeting of the Connecticut Medical Society, at New Haven, May 25, 1893, and printed in the Medical Record on July 23d, I called attention to the use of hydrogen dioxide for the purpose of disinfecting the abdominal cavity in cases of septic infection, having used it largely in surgical work, and found it non-irritating and more efficient than anything else in sepsis. At the time the paper was read I had only used it once in a case of septic peritonitis following a perforation of the intestines; the patient, however, dying soon after the operation, no deduction could be drawn from the use of dioxide.

At this time I wrote to several prominent surgeons, asking their experience, if any, in the use of dioxide in the general cavity; and their replies, with one exception, showed that the use of dioxide in the manner specified had not been attempted. In the excepted case, both patients operated on died shortly afterward.

Recently I have had occasion in two cases to use it, and instead of a weak solution have used it of full medicinal strength.

In the first case, September 6th, in the course of the removal of a purulent ovarian cyst, parts of the contents escaped into the general cavity. Half a pound of hydrogen dioxide of full medicinal strength was poured into the cavity, and the patient made a prompt and uneventful recovery.

In the second case, September 13th, a boy of sixteen, resection of the small intestine (Maunsell's method), an escape of fecal matter into the peritoneal cavity was followed by the use of a liberal quantity of dioxide, and although general peritonitis and fibrinous exudation in the intestine was present at the time, the peritonitis subsided, the temperature never rose as high after the operation as previous to it, and the boy up to date has made a good recovery. Both these cases are of too recent date for a detailed report at present, but will be given fully hereafter.

My reason for this hasty communication is that my recent experience proves that in dioxide we have a safe, non-irritating, and certain disinfectant for the peritoneal cavity, which ought to be universally known.

65 West Thirty-sixth Street.

Progress of Medical Science.

Therapeutic Effects of Altitude.—Dr. de la Harpe divides altitudes into three principal zones: (1) The sub-Alpine zone, between 700 and 1,300 metres; (2) the Alpine zone, up to 1,900 metres; and (3) the hyper-Alpine zone, above that height. The first of these is considered most suitable for invalids suffering from cardiac affections, atheromatous changes, those advanced in years, and excitable subjects, while a higher altitude gives excellent results in tuberculous, anæmic, and neurasthentic cases. With regard to the properties of the mountain air, the chief factors of the climate mentioned are: (1) The lowering of the temperature, at the rate of 1° for every 170 metres in the Alps; (2) the energy of insolation; (3) the dryness, and (4) the purity of the air; (5) diminished atmospheric pressure. Those unaccustomed to the climate of these altitudes must become acclimatized; the process takes some days, perhaps a week, during which the appetite increases, thirst is intense, respiration more frequent, the number of cardiac pulsations augmented, and the blood-pressure diminished. The quantity of air inspired increases, as also the amount of carbonic acid expired. Insomnia is at times very troublesome. Frequent palpitations and dyspnœa occur, especially in cardiac, anæmic, and fatty subjects. Once acclimatization is complete the sleep becomes natural, palpitations cease, respiration and pulse fall to normal, but the quantity of inspired air is slightly increased, while the blood is found to contain more corpuscles. This diminished atmospheric pressure exerts an influence on the circulation, accelerating it and raising the blood-pressure and tension of the pulse; the blood-vessels are fuller and nutrition is improved, thus affording excellent conditions for the treatment of anæmia and feeble cardiac innervation. The action of the dry and pure (free from microbes) air makes itself especially felt in certain pathological conditions; for example, the pus of suppurating, tuberculous, or pleural cavities undergoes diminution, the favorable process of sclerosis of the tissues surrounding the cavities is accelerated, and the cold of high altitudes rendered more supportable.—*British Medical Journal.*

The Treatment of Erysipelas.—Kolaczek (*Centralbl. für Chirurgie*, 1893, No. 28, p. 601) calls attention to the advantage of an occlusive dressing in the treatment of erysipelas, particularly as seen in surgical practice. For this purpose he employs what he designates as "rubber paper," which at first he moistened with a five per cent. solution of carbolic acid and had extend well beyond the margins of the affected surface. Latterly he has discarded the use of carbolic acid in this connection,

as he found that it caused the paper to adhere to the skin to which it had been applied, so that its removal was attended with difficulty and distress. Over the dressing is placed a compress of cotton and a firm bandage. The dressing is changed after the lapse of twenty-four hours and a larger piece of rubber or additional strips are applied if the process has extended. The efficacy of the treatment is supposed to depend upon the suppression of the perspiration that results, the unexcreted metabolic products being thought to have a destructive or inhibitive action upon the streptococci. The success of the procedure depends upon the accuracy of the approximation of the dressing to the surface.—*Med. News.*

The Passage of Fat into the Urine.—The conclusions drawn by Chabrié from the facts which he has gathered are, that the passage of fatty substances into the urine may be due to a variety of causes which he tabulates under four heads:

1. The presence in the blood of a parasite, the filaria sanguinis hominis. Investigation has shown here that the function of the kidney relative to the secretion of its normal constituents is not modified.

2. Certain pathological states, and in particular that of a form of Bright's disease. The lipuria is always very light.

3. The ingestion of quantities of fat.

4. Intestinal retention. In this case it is necessary to distinguish between the effects produced by an experimental or pathological ligature in man or in the dog. In the first, a retention of twenty-four hours is sufficient to produce the passage of fat into the urine; in the latter forty-eight are required. The author's theory is that this form of lipuria is produced by the resorption of bile, and he has produced it by injection of bile into the abdominal cavity of animals. Chyluria may be, therefore, a disease of the liver.—*Journal of Cutaneous and Genito-urinary Diseases.*

New Mode of Demonstrating Microbes which do not Stain by Gram's Method.—Dr. Nicolle describes a method of demonstrating some bacteria which are otherwise difficult to differentiate. The method depends on the property possessed by tannin of converting methylene blue fixed in the preparations into an insoluble form. The method of procedure is as follows (*The British Medical Journal*): The sections are hardened in alcohol, and stained for two or three minutes in Loeffler's or Kuhne's blue; they are then washed in water, after which they are passed through a 1.10 solution of tannin, the action of which is almost instantaneous; the sections are then washed again in water, dehydrated, cleared in oil of cloves or bergamot, and mounted in xylol-balsam. A greater contrast can be obtained between microbes and tissues if the sections, after being stained, are slightly decolorized by immersion in a feebly acid water. The histological elements are thereby more decolorized than the bacteria. In this manner the author has succeeded in obtaining excellent results in sections of glanders, typhoid, hog cholera, chicken cholera, soft chancre, etc., a thing which is by no means easy when the old methods are employed.

Gall-stones in the Intestines.—There are a large number of cases on record in which obscure cases of intestinal obstruction have proved to be due to the impaction of gall stones at some part of the intestinal tract. These cases are interesting from several points of view, and especially on account of the difficulty in diagnosis which many of them present. Of course when one has to do with a patient who is known to have suffered from jaundice or from occasional attacks of biliary colic, the possibility of the obstruction being caused by the impaction of such calculi must occur at once to the surgeon; but, except in cases where the obstruction is due to the agglomeration of several freshly formed calculi, there is often a curious absence of previous symptoms pointing to calculous formation. Yet in these very cases the stones are frequently of considerable size, so large in fact that they could not possibly have passed through the common bile duct by any conceivable degree of dilatation. They have indeed ulcerated through the gut by a slow necrotic process devoid of painful manifestations. Under these circumstances an exact diagnosis must be difficult, not to say impossible. The matter is, however, of some importance, because one is, of course, anxious to spare the patient the danger attending so serious an operation as laparotomy with incision of the gut, the more so seeing that a very large proportion of such cases are amenable to medicinal and general measures. It is probable that the failure to elicit the history of previous symptoms of hepatic colic is sometimes due to the inquiry being restricted within too narrow limits. It is indeed necessary to go far back in the patient's history to obtain the desired date, which may have been forgotten or overlooked. Fortunately the effect of surgical intervention in the more urgent cases is very satisfactory, provided it be had recourse to in good time.—*Medical Press.*

Rheumatism and Arterio-sclerosis.—Dr. Manteuffel discusses the relation of so-called rheumatism in the lower extremities and vascular disease. The pains complained of are situated in varying parts of the feet and legs, the feet are cold, and numbness may be experienced. The skin looks pale, and is often desquamating in minute scales. Sometimes patches of characteristic erythematous œdema may be seen with an increase in the symptoms above described. In these cases the pulses should be carefully examined. Differences may be present, and the arteries may be found degenerate. These manifestations are not to be confounded with articular affections, nor with sclerosis of the veins. No varices or pigmentation are present. Localized œdema is, of course, not to be mistaken for more general œdema due to venous obstruction. It may be difficult to distinguish this affection from neuralgia, and in cases of arterio-sclerosis the nerves may also be involved. For proof from morbid anatomy the author refers to cases of angio-sclerotic gangrene slowly developed and preceded by pains. He cites a case of gangrene in a girl, nineteen years of age, with diseased arteries, in which rheumatic pains had long preceded the gangrene. As to whether these rheumatic pains are a preliminary stage to gangrene cannot be denied with certainty in some cases. If the collateral circulation is insufficient, gangrene occurs, but this last stage is often not seen. The author warns against local massage in these cases of arterio-sclerotic rheumatism. Some patients whose disease is written of as rheumatism, or even hysteria, thus really suffer from arterio-sclerosis.—*Deutsche Medicinische Wochenschrift.*

Typhoid Empyema.—Dr. Weintraud records a case of empyema beginning in the second week of an attack of typhoid fever of moderate severity. The patient was a young man, nineteen years of age, and he made a good recovery without operation, although, at the beginning of the fifth week, he was seized with symptoms which pointed to peritonitis. At the end of the fourth week an exploratory puncture was made, and a syringeful of yellow, viscid, slimy pus was drawn off. Microscopical examination and cultivation experiments showed that this pus contained only a small bacillus, which was recognized as the typhoid bacillus. Seventeen days later, and after the patient had recovered from the symptoms of peritonitis, a second exploratory puncture was made, and similar yellow pus drawn off; it was again found to contain the typhoid bacillus in pure culture. The virulence of the bacilli was tested on both occasions on mice, and the interesting fact appeared that those withdrawn by the earlier puncture were far more virulent than those obtained on the second occasion, two weeks and one-half later. Weintraud points out that the case affords fresh proof of the fact that the typhoid bacillus is a pyogenic organism, and of the truth of the view expressed recently by Valentini and by Lorigo and Pensuti, that the bacillus

may be the direct cause of the production of empyema as a complication of typhoid fever.—*Berliner Klinische Wochenschrift.*

Profound Cerebral Symptoms in Adults from Indigestion.—That profound cerebral symptoms may appear in adults, as well as in children, as the result of errors in diet, is well illustrated by two cases recorded by Cortial (*Archives de Méd. et de Pharm. Milit.*, No. 7, p. 56). One occurred in a man, twenty-three years of age, who fell unconscious upon the street and was thought to have suffered a cerebral hemorrhage. About six ounces of blood were withdrawn and an ice-bag was applied to the head. All four members were agitated by movement, which was a little more marked upon the right than upon the left; the head was in constant motion; the eyes were turned upward and inward; the pupils were contracted; trismus was present; the pulse was rapid and regular; fever was moderate. The sphincters were continent; there was no hemiplegia The stomach was distended, and, notwithstanding the state of consciousness, pressure evidently induced pain. As cerebral hemorrhage is exceptional in young persons, alcoholism, indigestion, insolation, and heat-exhaustion were considered. The evidence pointed to indigestion as the cause of the symptoms, and, accordingly, a further bleeding of ten ounces was practised; dessertspoonful doses of infusion of tea were administered; a purgative enema of senna was given; the epigastric region was gently cauterized; and massage of the abdomen was from time to time performed. In a short while the patient began to vomit, bringing up the remains of some salad taken the day before; copious stools also followed. Consciousness was only gradually resumed. It was, however, two weeks before the man was quite restored. He related that he had not been exposed to the sun or to intense heat, but that on the day before his attack he had partaken of some salad, and that on the day of the attack he had eaten nothing, on account of a severe headache and a feeling of malaise.

The second case occurred in a vigorous man, twenty-six years of age, who was found unconscious, with eyes fixed; pupils contracted; respiration deep and a little stertorous; marked agitation of all four members, but especially upon the right, and without contracture; full but not rapid pulse; warm skin and hot head. He had been in good general health, suffering, however, with an attack of migraine about once a week. On three successive days there had been epistaxis. Stool had been painful and difficult The man had gone to bed without making a complaint, but toward midnight he was heard to groan, and then was found unconscious and in active convulsive movement. Other attacks occurred and were seen to be epileptiform in character. The parents asserted that the man had never had such attacks before. Indigestion being suspected, examination showed the abdomen to be distended and the percussion-note over the stomach to be dull. Strong pressure in the epigastrium appeared to induce pain and to excite a convulsion. After a bleeding of sixteen ounces the patient opened his eyes and became conscious. Abundant vomiting followed the ingestion of several cups of weak infusion of tea, bringing up imperfectly masticated meat. Purgatives were also administered, and in the course of a few days the patient was restored to his usual health. The distinguishing features of cases in which indigestion gives rise to cerebral symptoms are the fulness of the abdomen, with pain on deep pressure, and absence of modification of the respiration.—*Med. News.*

The Treatment of Sciatica.—Dr. E. Valentine Gibson has published an analysis of one thousand cases of sciatica, with special reference to one hundred cases treated by acupuncture. The results on discharge from the hospital of one hundred consecutive cases of sciatica treated by acupuncture are as follows: 56 per cent. were cured, 32 per cent. were much improved, 10 per cent. were improved, and in 2 per cent. there was no improvement. These results are satisfactory, considering the chronic nature and the severity of the majority of the cases. All these were treated by acupuncture, and they all used the Buxton thermal water, which has such a great reputation for the absorption of inflammatory products. Acupuncture the author considers very valuable. Dr. Gowers states: "Simple acupuncture along the course of the nerve has been recommended; it gives temporary relief, as does any superficial pain, but the cases are very few in which it has a permanent effect." The writer believes that Dr. Gowers refers to cutaneous acupuncture and not to acupuncture of the nerve itself, which was the method employed in these cases. The patient can always tell when the nerve has been pierced by pain shooting down the leg. The needles ought not to be left *in situ* for any length of time, but withdrawn immediately, as unless this is done severe pain is often caused on their withdrawal, and no better results seem to follow this line of treatment. A single spear-pointed needle two and a half inches long is all that is required, as the depth of tissue to be pierced can be regulated according to the situation and the development of the patient. If the nerve is not pierced on the first introduction of the needle, it can be partially withdrawn and entered again at a somewhat different angle, and in this way the nerve may be pierced in several different places with but one cutaneous puncture. The nerve should be pierced about five times over the parts where there is pain on pressure. The external popliteal nerve to the inner side of the biceps tendon may also be pierced if it is painful, and as it is not covered by muscle this can easily be done. There is often pain situated on the outer side of the leg, which in all cases is probably due to "referred pain." The musculo cutaneous nerve may be punctured along the whole of its course, but being of small size and lying deeply, it is naturally more difficult to pierce; but, even if the nerve is missed, the needle, passing in close proximity, must exert counter-irritation. These cases, without exception, he considers were due to an inflammation of the nerve-sheath, this affecting primarily the adventitious tissue, and in more severe cases spreading into the interstitial tissues—a perineuritis and an interstitial neuritis respectively. This condition would account for the various symptoms, sensory and trophic, such as pain, tingling sensations, and the wasting of muscle supplied by the affected nerve, and also those supplied by the small sciatic, when the disease affects the lower portion of the sacral plexus. The author, in view of his lack of opportunities for post mortem examination, quotes from Dr. Gowers: "In most cases that have been examined distinct evidence of neuritis has been found, chiefly involving the nerve-sheath, but extending in some cases into the interstitial tissue. In recent cases there are small hemorrhages, and in seven cases similar but slighter alterations in the interstitial tissue with secondary damage to the nerve-fibres. The signs of inflammation are most intense at the sciatic notch and opposite the middle of the thigh. They may be limited to one or both of these places, or they may be greatest there and extend in slighter degree over a considerable tract of nerve." Considering this to be the true pathology of sciatica, the treatment by acupuncture is a rational one, more especially in the earlier stages of the disease; but even in the later stages puncturing the thickened nerve-sheath may promote absorption. If the nerve is pierced in a number of places over the inflamed area, where there is congestion of vessels and consequently exudation of serum and small-celled infiltration, it must be given an outlet, however small, to more or less of the exudation; also dilated blood-vessels must be pierced, thus relieving tension in two ways and favoring the process of absorption. Rest is necessarily most essential, as it is in other inflammatory conditions. A rheumatic or gouty diathesis should be treated by appropriate remedies, as they are often a predisposing cause. The more chronic the sciatica the more difficult is the cure, as organization of the effused material must be a source of irritation and a nidus for subsequent relapses. In cases of secondary sciatica,

due to rheumatoid arthritis of the hip-joint, a slight temporary relief only is obtained by acupuncture, as the source of irritation cannot be eliminated. Whether this irritation is due to pressure of the enlarged capsule of the joint on the nerve or to the changes in the joint, giving rise to a neuritis of the nerve-fibres supplying the joint, and spreading from there to the trunk of the sciatic nerve, is a point requiring investigation.

In conclusion, if every case of sciatica, beginning acutely or subacutely, were to be treated by absolute rest, together with acupuncture, repeated, if necessary, at intervals of a few days, and at the same time any rheumatic or gouty tendency were treated by suitable remedies, the author does not think there would be the number of chronic and relapsing cases that one so often sees.—*Therapeutic Gazette.*

Ureterectomy.—Dr. Reynier reports a case in which he removed the whole of one ureter. The patient first came under treatment in April, 1892, when he gave a history of typhoid fever in February, 1891, and two months later more pain in the lumbar region, followed by albuminuria and then pyrexia (*British Medical Journal*). The urine was purulent at intervals, and micturition painful. At this time the existence of a pyonephrosis on the right side was diagnosed. On May 27th nephrectomy was performed, when the kidney was found to be a purulent cyst. The peritoneum was opened at the operation, but was returned without allowing local infection to occur. The ureter was fixed in the lower part of the wound. Fifteen days after the operation pus still flowed from the end of the ureter in the wound, the temperature still remained raised, and on cystoscopic examination drops of pus were seen exuding from the opening of the right ureter. Washing out of the ureter was next practised, but without any good result. A further operation was now performed. The lumbar wound was enlarged, and 12 ctm. of the upper end of the ureter removed. The fistula still remained and no good result followed. On November 18th an incision was made in the right inguinal region, and the peritoneum stripped up until the remains of the ureter were reached. It was dilated even to its junction with the bladder. The whole of the ureter remaining was now removed. On the following day pus had disappeared from the urine. On January 21, 1893, the patient was discharged completely cured. According to the author, this is the first case of complete removal of one ureter. He recommends that when ureteral accidents occur after nephrectomy, especially in tuberculous cases, the affected ureter should be completely removed by an inguinal incision and stripping up of the peritoneum.

Emol is the discretional name given by Dr. W. Allen Jamieson (*Brit. Med. Journal*) to a natural product, refined and purified by various intricate processes, but unsophisticated in any way. He has had the opportunity afforded of seeing the substance *in situ*, and of following all the stages through which it passes till it emerges as the delicate, soft, impalpable powder. The material from which emol is prepared is found in large quantity near Dunning, in Perthshire, where it occurs in close association with serpentine marble, chalcedony, onyx, and copper. It has been examined and analyzed by Dr. Readman, F.C.S., who finds that it is allied to fuller's earth, yet is distinct from most, if not all, varieties of fuller's earth hitherto in the market. Emol contains steatite as well as silica, alumina, with a mere trace of lime, and it is probably to the first ingredient named that its peculiar properties, summarized in its adopted designation, are due. The delicate pink tint which it exhibits is owing to the presence of a very minute quantity of oxide of iron. When placed on the tongue there is an absence of the sensation of grittiness so perceptible when fuller's earth of the ordinary kind is tested in a similar way. The first effect noticed when a small quantity—say a teaspoonful—is mixed with a hard water, such as is met with in limestone districts, in a basin, is its immediate softening influence. Used in this manner with warm water it acts as a natural soap, cleansing the hands, and at the same time leaving them soft and smooth. The workmen engaged in its preparation found that their previously horny palms became so much altered by continued contact with it that they were no longer fit for active manual labor, assuming, as one of them remarked to me, a softness more like that of a lady's hand; they could not use their hands for any employment which exposed them to friction. This experience led Dr. Jamieson to try it for the purpose of softening and removing those horny accretions encountered in some states of keratosis of the palms and soles. For the treatment of these salicylic acid in some form or another has hitherto proved the most effectual agent, but its application is accompanied with considerable pain, though otherwise successful enough for a time, if not permanently. When, however, a magma of emol was made by moistening some with water, so as to form a paste, applying it pretty thickly, and preventing evaporation by covering with an impervious material, such as oiled silk or guttapercha tissue, the epidermic masses became softened and loosened, and could be peeled off in layers, eventually leaving the part so treated soft, smooth, and pink in hue. In this way he was able to remove the hard, horny epidermis in several cases of eczema of the palm and sole. One of these cases was that of a gouty lady, tall and stout, in whom many different methods of management had been before tried with but indifferent effect. In her case the subsequent application of unguentum vaselini plumbicum, spread on cotton, had the result of restoring a healthy cuticle, which enabled her to undertake a prolonged continental journey with ease and comfort.

Retention of Lochia.—Dr. Jacobsen has published a communication on lochio-metra, or distention of the uterus with retained lochia. A multipara did well for five days after normal labor. Then fever, rigors, and enlargement of the uterus occurred. The cervix was found to be stopped up by a tumor which was removed, the unfavorable symptoms ceasing directly afterward. The tumor formed a mass of whitish jelly, about as big as a middle-sized pear. Some young connective tissue and small vessels were found in it. Hence it was probably the remains of a large old coagulum, the result of hemorrhage at about the beginning of the third month of pregnancy. It is of interest to note that at that stage in previous pregnancies the patient had regularly aborted; but in this last pregnancy she had kept her bed at the same stage and warded off abortion. Notwithstanding the high fever which preceded the removal of the tumor, the fluid lochia which escaped afterward was neither discolored nor fœtid. The tumor had sealed it up. In reply to a question, Jacobsen stated that before the removal of the tumor the uterus stood high in the pelvis, whether the bladder were full or empty. Schräder attributed fever in childbed partly to exhaustion of the uterus after severe pains; absorption was then favored. When the uterus was at rest physiologically, it might hold putrid lochia without fever being produced.—*Centralblatt für Gynäkologie.*

Medical Treatment of Hæmorrhoids.—Dr. Paul Reclus (*Rev. Gle. de Clin. et de Thérap.*, April 5, 1893) details his mode of using cocaine in the treatment of hæmorrhoids. For the constipation he advises laxatives, enemata, and perineal fomentation with water at 50° or 55° C. (122° to 131° F.); he also suggests that before each passage a small piece of absorbent cotton, the size of a pea, which has been dipped in a two per cent. solution of cocaine, should be introduced into the rectum. Immediately after the defecation, the perineal fomentation should be repeated if there be pain, and another piece of cotton with cocaine introduced. If hæmorrhoids be voluminous and congested, Professor Reclus advises dilatation of the anus after the local application of cocaine, and injections of the same substance in the sphincter.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, October 7, 1893.

SHOULD WOMEN SMOKE?

SOME years ago, under the stimulus of Mr. James Parton, there was much discussion over the questions, "Will the coming man drink wine?" and, "Will the coming man smoke?" Both these questions have been answered in the affirmative so far as the nineteenth century is concerned. A more serious question is now agitating the English public, and it is simply this: "Will the coming woman smoke?" It appears that the habit of smoking cigarettes is increasing among a certain class of English women, and we refer to respectable women; for the prostitute has always been addicted to the cigarette. There have appeared public defenders of the practice. The plea is that if men smoke, women ought to be allowed to do it also; that the habit, if practised at the proper places and times, is not an offensive or indelicate one, nor particularly injurious. Looking at the question from a purely medical point of view, we doubt if the practice of smoking will be sanctioned by science or experience. Tobacco is undoubtedly a depressing, though agreeable, poison. It is particularly injurious to persons of an emotional and over-sensitive nervous system, and hence it would harm more women proportionately than it does men. Aside from this, we regret to say that lovely woman is less to be trusted with narcotics and stimulants than man—and the latter animal is weak enough. Hence excess and abuse of the narcotic would be more frequent.

Perhaps most of our readers will think it foolish even to treat seriously such a proposition as that which we are discussing. But these are *fin de siècle* times, and no one knows what bizarre fashion may suddenly become the rage. Most emphatically we should say that the coming woman, as well as the woman who has already come, should not smoke. She can win the heart of the smoker, but she should beware of the smoker's heart.

THE NEW YORK INFANT ASYLUM AGAIN.

THE *Sun* publishes the following:

When eighteen physicians connected with the New York Infant Asylum resigned last May, because, as they said, they had been treated discourteously and unfairly by President Knickerbacker and the Board of Managers, the MEDICAL RECORD, in discussing the affair, said:

"In this case we do not see that any other course could be taken by the Medical Board: furthermore, it is difficult to see how any self-respecting physicians can take their place. Such a position is not and would not be tolerated by any Board of Visiting Physicians, however great the attractions of the service. We shall watch with interest for the list of gentlemen who accept the positions thus vacated."

It looks now as though the RECORD'S watch would not be relieved in a hurry. The first meeting of the Board of Managers of the asylum since the resignations were offered was held recently, and no physicians were appointed to fill the vacancies.

There is now but one visiting obstetrician where there were four, two visiting physicians for the treatment of diseases of children where there were five, one consulting obstetrician, no gynecologist, no orthopedic surgeon, no physicians for nervous or mental diseases or diseases of the throat, and no ophthalmic or aural surgeons. Heretofore several operations a week have been performed at the hospital at Tenth Avenue and Sixty-first Street, many in gynecology ranking among the most notable in the country.

There are, as will be seen, now only four physicians connected with the institution, and three of these were, we believe, members of the old board.

So far, it seems that reputable physicians have wisely fought shy of an institution whose executives have affronted and attempted to degrade the medical staff. We are convinced that the one obstetrician who accepted a place must have done so under a misunderstanding.

The issues in this case were very clear, but they might well be emphasized again. The medical board, without warning, was deprived of its right to nominate or have any voice in the appointment of its associates. Furthermore, attempts to secure an understanding were met with affronts and discourtesy by an ignorant and obstinate executive.

We have no doubt that in time the organization of the Asylum will be so changed that incidents such as have occurred in the past year will be made impossible. The institution is a useful charity, and its managing board contains many gentlemen who would not knowingly be a party to injustice and folly. But until some change is made, we can but repeat that self-respecting physicians will have nothing to do with it.

IMMUNIZING AGAINST YELLOW FEVER.

A GOOD deal of comment was naturally aroused by the report that Dr. Murray, of the U. S. Marine Hospital Service, who is stationed at Brunswick, Ga., had sent for his family to join him in the infected region. Such action would be likely to give confidence to many that the violence of the epidemic was abating. The true reason, however, is stated in a note from Dr. Murray to Surgeon-General Wyman, in which he says:

"I desire to have my three younger children, aged seven, eight, and thirteen, to be immunes as soon as possible to save them from annual scare and worry. My two older daughters, aged fifteen and seventeen, are immunes, but are now in college. I have perfect confidence in my skill, and do not fear that anyone will die if I treat them. In view of your telegram I have directed them not to come, not wishing to displease you, and if you forbid, will stop them. I consider the chance a lost one."

It is evident that Dr. Murray regards an attack of yellow fever as harmless as measles when properly treated. Such a view should be most consoling to those who are forced to remain in infected quarters and take the chances of the disease. The total mortality-rate in the present epidemic has been relatively low (about fifteen per cent.).

THE MUNICIPAL DISTRIBUTION OF HOMŒOPATHY.

Cleveland, O., seems to be the garden-spot of homœopathy if we may judge from the statistics given in *The Cleveland Medical Gazette*. Out of a total of 527 physicians, 139, or twenty-six per cent., are homœopaths. In a few Western cities, such as Cincinnati, Indianapolis, and Columbus, the percentage is about six, but in the majority the average is much higher. Thus Chicago has 348 homœopaths out of a total of 2,700, or twelve per cent.; Detroit, 59 out of a total of 482, or twelve per cent.; St. Paul, 26 out of a total of 200, or thirteen per cent.; Minneapolis, 46 out of 328, or fourteen per cent.; Pittsburgh, 54 out of 383, or fourteen per cent.; Allegheny, 17 out of 156, less than eleven per cent.; Philadelphia, 346 out of a total of 2,380, or fourteen per cent.

In New York City, the simon pure homœopath is rare, and very few homœopathic signs are to be seen. Among 3,400 physicians, probably less than ten per cent. are homœopaths, as against fourteen per cent. in Philadelphia, and twelve in Chicago. The disappearance of all strife between so-called schools has, no doubt, had much to do with this. The distinctions between the schools are daily becoming more nominal.

LIFE.

Many can recall the time, for it is barely twenty years ago, when scientific and public interest was much centred on the question what is "life," or what is the nature of the vital principle, if such a thing exists. Dr. Bastian, and Professor Huxley, Mr. Tyndall and various other eminent biologists and physicists were then very much in evidence, to say nothing of the theologians. It became pretty well settled at that time that there was no such thing as spontaneous generation, or that by no human means could chemical action be changed into vital action. The living, structureless ooze of the sea possessed some function which could not be imitated in the most richly equipped laboratory. There was some comfort in this to the conservative minds. On the other hand, it became generally acknowledged that the physical basis of life, that is to say, of vital activity, was, as Professor Huxley asserted, a protoplasm of some kind. Furthermore, physiologists very generally gave up the ancient view that life was dependent upon some special principle or force which entered into and acted upon the organism like a kind of *Deus ex machinâ*.

In place of this view, which was long and tenaciously held in particular by the Montpellier school, it was taught that vital activity was only another mode of energy; that it was derived from heat, electricity, chemism, motion, and was transformed into its equivalent during life and at death.

This, which was called the mechanical view of life, is the doctrine still adhered to and still taught. But it would follow that, if this is the complete solution of the question, life ought to be artificially produced. Man can transform heat to light, light to motion, motion to electricity, electricity to chemism. He has even succeeded in showing a practical identity in the energies known as heat, light, electricity, and magnetism. These are all but variations in the motion of the ether. But as yet science has made no progress whatever in transforming any phase of energy into vital activity. He cannot manufacture protoplasm. In his recent Presidential address before the British Association, Professor Burdon-Sanderson took up again the subject of "Life," and announced most positively the conclusion above stated. Philosopher, physicist, chemist, all are exactly where they were twenty years ago, and they have to fall back upon some theory of meteoric dust or extraordinary prehistoric cosmic conditions in order to explain the appearance of life upon this planet.

With science thus at a standstill we may the more readily pardon the intrusion of the imagination upon the subject of what is vital action; and Sir Benjamin Ward Richardson offers to the world in his "Æsclepiad" some interesting phantasies anent this subject. Sir Benjamin has a theory of nervous ether which will, he thinks, account for the vital phenomena of the nervous system at least. He assumes that there exists in this part of our anatomy a certain ethereal fluid which is secreted from the blood and which varies in tension, amount, and quality with the various changes of the body and its environment. In fact, Sir Benjamin's essays read like a modernized edition of an ancient medical classic. The inventor of this nervous ether has tried to condense it, bottle it, and even manufacture it, but, as he admits, so far without much success.

It appears to us that the ingenious editor of the "Æsclepiad" is calling up a ghostly fluid which unnecessarily complicates things. Life is a kind of chemism which is peculiar in that it transforms its energy not only into heat, motion, electricity, and chemical action, but produces in addition ethereal vibrations that are various and complex in their result. Nerve-currents, and the secretory and reproductive activity of cells are examples of this. As yet we can only suppose these to be modes of motion of the ether, and it is not necessary to invoke a new kind of fluid for the nerves, because, if we do, we will have a secretory and reproductive ether as well as a nervous one. The experiments which demonstrated that light was a form of electricity were brilliant, ingenious, and convincing. Perhaps some day we may be able to analyze the activities of the living cell, and measure its vibrations, but the problem is immeasurably more complex than that solved by Herz. And it is meanwhile very restful to believe that the Lord himself first infused into dust the breath of life. For undoubtedly He did.

Tannate of Mercury being unchanged in the stomach, and only decomposed after it enters the alkaline contents of the small intestine, is incapable of producing gastric irritation, and since we calculate to introducing something like two ounces of mercury by way of the stomach during an antisyphilitic course, it becomes very necessary to give it in such a way as not to upset the stomach, and hence our calculations.—Allen.

News of the Week.

Death of Dr. E. A. Maxwell.—Dr. E. A. Maxwell, who died September 25th, was graduated from the Bellevue Medical College in 1869. Soon after his graduation he was appointed visiting physician to Randall's Island and Charity Hospitals, and for fifteen years he served as pathologist to the latter institution. At the time of his death he was consulting physician to Randall's Island Hospital, and consulting pathologist to the City Hospital.

The Académie de Médecine of Paris has had two successive sessions without being able to secure a communication to be read. The attendance was very small. It is proposed to add to the membership in order to get some life into the ancient institution.

Collodion in Hemorrhoids.—Dr. Becelaere, of Detroit, Mich., writes: "A friend has to-day called my attention to an article by A. H. S——, criticising the use of collodion, which I recommended in a paper on 'Hemorrhoids,' published in your MEDICAL RECORD for July 29th last, on the ground that 'solidified collodion is simply gun cotton' (*sic*). It never struck me that gun-cotton and collodion were identical. I always held, and still believe that pyroxylon is one thing, and its ethereal solution another. Would anyone, for instance, claim that rosin and varnish are identical? I know from actual experience that gun cotton will 'fuse,' if touched with a burning match, and also that thoroughly solidified collodion will burn under identical circumstances if presented edgewise. I am, however, in position to maintain that a thermo-cautery knife at a brown heat will go through spread, solidified collodion very much the same as through a piece of bacon, and this without causing the least 'fusing' or igniting the protective layer. If A. H. S—— will take the trouble to repeat the experiment for himself, he will at once be convinced that 'solidified collodion' is not 'simply gun-cotton.'"

Immunity from Scarlet Fever by Inoculation of Blood serum.—Dr. A. S. Ashmead, of New York, reports (*University Medical Magazine*) the case of a boy who had scarlet fever. On the seventeenth day Dr. Ashmead inoculated with his blood-serum, ten drops, his sister, a healthy girl, who had played with him, kissed him, and been in close personal contact during the disease. She did not become infected. Dr. Ashmead comes to the following conclusions: It is probable that the first inoculation of immune blood-serum gave protection to the girl. Therefore, there was no necessity for repeated inoculation. I think I am justified in believing that the assertion of Ogata and Jasuhara, of Tokio, that even one drop of immune frog's blood, or half a drop of immune dog's blood, is sufficient to protect a mouse from the fatal effect of an anthrax inoculation, states at least a probable fact. The streptococci had nothing to do with the disease. The boy's serum, on the eighteenth day, when inoculated into his sister, was not infectious. The albumin of scarlatinal nephritis is not toxic. The inoculation of scarlet fever with immunized blood serum is not curative. The inoculation, without infection of the girl, with ten minims of blood serum from a second boy, who had not been immunized, apparently proves the immunity conferred by the first inoculation. I add two practical suggestions: The application of a blister over the kidneys in scarlatinal nephritis is followed by good effect. The earliest symptom of improvement in this complication is the appearance of urates and uric acid crystals in the urine.

Danger in Pencils.—It has been the practice in the public schools of St. Paul, Minn., for the janitors to collect all the lead and slate pencils after school hours, and distribute them indiscriminately in the morning. Health Commissioner Hoyt has requested that hereafter each pupil retain his own pencils, as there is reason to believe that diphtheria and other diseases have resulted from children putting in their mouths pencils that have been used by others.

A Wedding Delayed by a Misfit Leg.—A misfit wooden leg was the cause of the postponement of a wedding in Pittsburg, Pa., on September 20th. Joseph Smith and Annie Nugent had been sweethearts a long time, but an accident by which the former lost a leg deferred the wedding. The girl had some objections to marrying a one-legged man, but the cripple soon overcame her objections and the marriage was set for that time. Among other articles of wearing apparel the groom ordered was a brand-new wooden leg. The artificial limb was sent to the house the day before. When he found it did not fit him Smith sent it back, and told his friends who had been invited that the wedding would be postponed until the misfit leg was repaired.

Active Gastric Dilatation.—In a friendly contest to see who could eat the largest number of ears of green corn, a New Haven woman got away with eighteen ears and suffered no subsequent discomfort.

A Touching Tribute to Medical Heroism.—The following touching tribute to medical heroism is from the New York *Sun*. The *Sun* is always just to the medical profession, and in this instance speaks, as it has often done before, from its heart: "One of the first victims of the yellow fever at Brunswick last month was a practising physician, who caught the infection from a patient upon whom he was attending. On Sunday last, one of the physicians of the New York Hospital, Dr. Walter Vought, died of typhoid fever, the infection of which had been communicated to him by a child in the hospital. Again, a few days ago, two young doctors of this city caught the small pox from a patient who was afflicted with it. There are always risks for doctors in attendance upon patients suffering from contagious or infectious maladies. Yet they are always ready to brave the danger, without flinching, in the interest of humanity. Honor to our noble army of doctors! Hundreds of them volunteered for service here last autumn, when the city was threatened with cholera. We do not know how many of them have sent word to Surgeon General Wyman that they stand ready to go to Brunswick, or to any other part of the South in which the yellow fever may break out. Whatever be the risks from any disease, the medical faculty is ever willing to confront them. Long live the doctors! We have sent American doctors to the cholera-infected ports of Europe, and several of them have done splendid work there this year. If a hundred of them had been needed, we have no doubt that a thousand of them would have

offered their services. Heroes are the doctors. They will enter a pesthouse without shrinking, attend to every case in it, and do all that can be done to relieve the sufferers. Blessed be the doctors! They are men of science, men of skill, men of earnest purpose, men of sympathetic disposition. They are devoted to their duties. Dr. Walter Vought, who died of typhoid fever last Sunday in the New York Hospital, of which he was house physician, was a man of talent, and still in his early prime. He took charge of the quarantine station at Fire Island last year during the 'cholera scare;' he had rendered service in the Vanderbilt clinic; he died in a hospital. Though he had but just turned thirty years of age, he was the author of works upon malarial fevers, the cholera, and other diseases; he had already won a name in the profession. We knew him personally, and we can testify that he was a high-minded gentleman:

> 'There's rosemary, that's for remembrance; . . .
> and there is pansies, that's for thoughts.'"

The Southern Surgical and Gynecological Association will hold its next session in New Orleans on the 14th, 15th, and 16th days of November. Members of the medical profession are cordially invited to attend.

Dr. José M. Ferrer has been appointed visiting physician to the French Hospital.

American Public Health Association.—The next meeting of this Association will be in connection with the International Congress of Public Health at the Art Institute Building, Chicago, Ill., October 9–14, 1893. First meeting of the Congress, October 9th, at 8 P.M.

Tri-State Medical Society of Alabama, Georgia, and Tennessee.—The fifth annual meeting of the Tri-State Medical Society will be held in the Unitarian Church, Chattanooga, October 17th, 18th, and 19th. The prospects are for a large attendance and a very interesting meeting.

New York State Association of Railway Surgeons.—The third annual meeting of the New York State Association of Railway Surgeons will be held under the presidency of George Chaffee, at the Academy of Medicine, in New York City, November 15th. A cordial invitation is extended to the profession.

The Army Medical School.—General orders, No. 78. Headquarters of the Army, Adjutant General's Office, Washington, September 22, 1893. By direction of the Secretary of War, upon the recommendation of the Surgeon General of the Army, the faculty of the Army Medical School, established by General Orders, No. 51, June 24, 1893, from this office, and regulations for the government of the school, are announced as follows:

Faculty of the Army Medical School.—Colonel Charles H. Alden, Assistant Surgeon-General, United States Army, President of the Faculty and Lecturer on the Duties of Medical Officers; Lieutenant Colonel William H. Forwood, Deputy Surgeon-General, United States Army, Professor of Military Surgery; Major John S. Billings, Surgeon, United States Army, Professor of Military Hygiene; Major Charles Smart, Surgeon, United States Army, Professor of Military Medicine and Director of the Chemical Laboratory; Captain Walter Reed, Assistant Surgeon, United States Army, Professor of Clinical and Sanitary Microscopy and Director of the Pathological Laboratory; Captain Julian M. Cabell, Assistant Surgeon, United States Army, Assistant to Professor of Military Surgery and Instructor in Hospital Corps Drill.

The Course of Instruction.—The course of instruction will be for four months, and will be given annually at the Army Medical Museum, in Washington City, commencing on November 1st. It will include lectures on and practical instruction in: 1. The duties of medical officers in war and peace. 2. Military surgery, the care of the wounded in time of war, and hospital administration. 3. Military hygiene. 4. Military medicine. 5. Microscopy, sanitary and clinical; pathological histology, bacteriology, and urinology. 6. Hospital corps drill and first aid to wounded. By permission of the Surgeon-General, medical officers of the Army who desire to avail themselves of the course of instruction, and who are stationed in or near the city of Washington, or who have a leave of absence which enables them to attend the course, may be admitted as pupils under the same regulations as apply to recently "approved candidates for admission to the Medical Corps of the Army."

Examinations.—At the termination of the course of instruction the "approved candidates for admission to the Medical Corps of the Army" will be examined by the several professors, and their relative proficiency in each branch will be reported by the president of the faculty to the Secretary of War through the Surgeon-General of the army.

Regulations.—1. The president of the faculty will be responsible for the discipline of the school. 2. The junior professor will act as secretary and will be responsible for all property pertaining to the school. 3. A faculty meeting will be held in the office of the secretary on the first Monday of each month from October to March, inclusive, and whenever called by the president of the faculty or the Surgeon General of the Army. 4. Resolutions adopted by the faculty relating to the course of instruction, the purchase of books and instruments, etc., will be submitted to the Surgeon General of the Army for his approval. 5. The president of the faculty will submit to the Surgeon-General of the Army, on or before April 1st of each year, a detailed report of the condition of the Army Medical School, including an account of the instruction given and the proficiency of the several pupils as shown by an examination made by each professor at the termination of his course. 6. The hours of instruction will be from 9 to 12 A.M., and from 1 to 4 P.M., daily, from November 1st to February 28th, inclusive, with the exception of Saturdays, Sundays, legal holidays, and the week commencing December 25th. 7. Pupils will be required to be present during the hours designated unless specially excused by the President of the Faculty or by orders from the War Department. 8. When necessarily absent on account of sickness or other emergency, pupils will, as soon as practicable, send a written statement to the secretary of the faculty, explaining the reason for such absence. 9. The laboratories and library of the Army Medical School will be open for the use of pupils during the hours of instruction designated. 10. Pupils will be held strictly accountable for all instruments and apparatus issued to them for their personal use during the course of instruction, and for any loss or injury to books or apparatus belonging to the Army Medical School, when such loss or injury is due to carelessness or neglect. 11.

Pupils in the Army Medical School, during the hours of instruction, will wear the undress uniform of the grade to which they belong, except when engaged in laboratory work, when a black cambric laboratory gown may be worn.

By command of Major-General Schofield ; R. Williams, Adjutant-General.

Death of Dr. Thomas J. Richards from Small-Pox.—Dr. Thomas J. Richards died October 1st, of small-pox, on North Brother Island, after being ill less than a week. He contracted the disease at the Vanderbilt Clinic during a lecture which was being held there over a man named McGowan. Dr. Richards and Dr. Charles Norris were taken ill and sent to North Brother Island on September 21st. McGowan was also sent there, and recovered. He caught the disease at 429 West Fifty-Second Street, where there were five other cases. Dr. Norris, we are glad to say, will probably recover.

The Cat and the Caul.—Mrs. Ella Johnson, who lives in Philadelphia, recently became the proud mother of a bouncing baby boy, and when it became noised about that the lusty youngster had come into the world decorated with a caul the happy mother was deluged with congratulations, which she received with becoming modesty, satisfied with the knowledge that her offspring, because of his lucky face covering, would be free from most of the ills and dangers of ordinary mortals. But in a few days Mrs. Johnson's joy was turned to mourning. The caul had disappeared. Suspicion fell upon a neighbor and professional nurse who had presided over the sick-room during Mrs. Johnson's hours of anxiety. Mrs. Johnson says the nurse stole it and sold it to a sea captain for fifty dollars. She accordingly had the nurse arrested, and yesterday Magistrate Hackett was stumped by the strange explanation. In her own defence the nurse declared that the Johnson household cat had stolen the precious caul from off the bureau. This story was not credited, but Magistrate Hackett confessed himself in a quandary, and held the case under advisement.

Dr. Thomas L. Stedman.—The numerous friends of Dr. Thomas L. Stedman, the talented member of the MEDICAL RECORD staff, will be pleased to learn that he is satisfactorily recovering from an attack of typhoid fever, from which he has been suffering for the past month.

The Coroners' System Condemned.—The Grand Jury, after a week of patient investigation of the abuses of the Coroners' office, has recommended that such systems of inquest be abolished and in their stead the Massachusetts plan of examination be substituted. The latter, which has worked in a very satisfactory manner, consists of the medical examinations by legal experts to determine the cause of death, after which, in case of suspicion of criminality, the case goes to the police court. The presentment of the Grand Jury will be duly laid before the Constitutional Convention for adoption.

Board of Health Resign.—Four of six members of the Columbus (Ga.) Board of Health, including the President, Dr. Ticknor, resigned because the city council refused to pass an ordinance of quarantine against Brunswick.

Homœopathic College. — The Louisville homœopathists have started a medical college in that city.

The Colorado Medical Library Association has issued the following circular: "Certain members of the medical profession in Denver, realizing that the existence of a medical reference library for Colorado has become a necessity to the enlightened study and practice of medicine, have united and become incorporated under the title of the Colorado Medical Library Association. The annual subscription for membership has been placed at $5, and the subscriptions so received will be expended in the purchase of medical literature of a character determined by the nominations of the individual subscribers. The works thus obtained will be placed on the shelves of the Denver Public Library, on the condition that the library will spend on medical literature at least as much money as is subscribed by the association. The power and usefulness of books are increased when they are brought together. To the choice collection of medical works already in possession of the Public Library, several hundred valuable volumes have recently been added, either as bequests, gifts, or to be held in trust for their present owners. The funds in the treasury of the Medico-legal Society have been devoted to the purchase of appropriate literature to be added to the library. The medical department of the library now contains over eight hundred bound volumes ; fifty-five journals are regularly received through subscription, while some seventy-five additional journals are present in incomplete sets. At the present rate Colorado will shortly be in possession of a medical library which will compare favorably with the collections of the East. The present Executive Committee is as follows: Dr. J. T. Eskridge, President ; Dr. Henry Sewall, Secretary and Treasurer, No. 23 Eighteenth Avenue ; Mr. J. C. Dana, Librarian."

The Uses of Thiocamf.—Duffey (*Dublin Journal of Medical Science*, May, 1893) has been led to use thiocamf as an intestinal antiseptic, a surgical application, and an antiparasitic in cutaneous affections. His communication has already been briefly alluded to in this journal. Thiocamf is described by Professor Emerson Reynolds, its discoverer, as a "liquid which results when sulphur dioxide gas is brought in contact with camphor." In this liquid are dissolved several substances destructive of bacteria, among them benzoic acid and phellandrene. Thiocamf can be preserved without pressure in bottles at ordinary temperatures, but on its exposure in thin layers a steady evolution of large volumes of sulphur-dioxide gas, charged with the vapors of other disinfectants, takes place. From this action it has been much used for atmospheric disinfection, and, for the same reason, Duffey has applied it to the uses noted. For internal administration it was combined with pure butter fat in the proportion of ten per cent. of thiocamf. Of this, ten grains were given in capsule every two or three hours for four doses. The capsules were sometimes coated with keratin, that they might pass through the stomach and be dissolved in the intestines. The drug was thus used in a case of typhoid fever, in a case of phthisis in which the patient was suffering from pyrosis, in a case of dilatation of the stomach, and in a case of alcoholic peripheral neuritis in which the patient had fetid alvine evacuations. In all of these the signs of fermentation became less marked and the character of the movements improved. In two cases of scabies a four per cent. solution in olive-oil effected rapid cures.

In bedsores and unhealthy ulcerations it was used in oily solution (four to six per cent.) with the effect of quickly removing fetor, diminishing the discharge, and promoting healing. No ill effect was noted in any case.

The New York Medical Association will hold its Tenth Annual Meeting on October 9, 10, 11, and 12, 1893, at Mott Memorial Hall, in New York City.

The Yellow Fever Epidemic.—The number of new cases of yellow fever during last week in the town of Brunswick, Ga., has been very nearly one hundred, and the ratio of deaths to cases has been about one to seven. The disease is likely to continue to exist there until it is killed by frost, and it is not probable that, in that latitude, there will be any frost for several weeks yet. About one-half of the people of the place succeeded in getting away from it as soon as the disease was known to be epidemic, but those who were left there on August 12th have been forcibly prevented from leaving since that time. The reports at the time of writing indicate that the disease is spreading slowly through the surrounding towns.

A Conference on the Care of Dependent and Delinquent Children will be held in the State of New York, under the auspices of the State Charities Aid Association of New York, in the Assembly Hall of the United Charities building, Fourth Avenue and Twenty second Street, New York City, Tuesday, Wednesday, and Thursday, November 14, 15, and 16, 1893.

Professor Von Helmholtz, of Berlin, has been visiting this country and was tendered a public reception at Columbia College, on October 3d, by President and Mrs. Seth Low. The room was brilliant with electric lights, and grouped here and there were potted palms. The Hungarian orchestra was stationed in one of the galleries. He was also entertained at the Century Club, October 4th. Professor Von Helmholtz rendered an enormous service to medicine and to humanity by his invention of the ophthalmoscope, in 1851. His work on physiological optics (1867) also contained much that contributed to the advancement of ophthalmological science.

A Medical College at Princeton.—A telegram from Princeton, N. J., says that steps are being taken which will doubtless result in the establishment of a medical school at Princeton. Dr. Patton stated in his opening address last week that Princeton could have a medical department within one month, but whether he or the trustees were in favor of it he would not state then. A meeting of the committee appointed by the Faculty to further plans for the School of Medicine was recently held at which three new electives were added to the course, namely, comparative osteology, practical botany, and human anatomy.

The following has been taken from the advance leaves of the catalogue: "Students who contemplate entering the medical profession may combine the electives in biology and chemistry so as to receive, when graduating, a special certificate recommending them to a second year's standing in medical colleges which have a four years' course. The new course will include the required academic classes in general chemistry, botany, and zoölogy, mechanics and general physics; also the following elective courses: Junior year, general biology and theoretical chemistry, practical botany, vertebrate anatomy, and histology; Senior year, laboratory chemistry, physiology, comparative osteology and vertebrate morphology, embryology, histology, and paleontology."

Pension Surgeon.—Dr. William R. Pryor has been appointed a pension surgeon on the Central Board in New York City, in place of Dr. J. C. Morton, who is a republican.

Dr. S. Fleet Speir's suit against the city of Brooklyn, for damages to his residence by fireworks during a political demonstration, has been decided in his favor for $10,000 damages and costs.

The Death of Dr. Walter Vought.—At a meeting of the New York Neurological Society, held October 3, 1893, the following resolutions were adopted:

Resolved, That it is with the deepest regret that this society has learned of the death of Dr. Walter Vought, one of its youngest and most promising members, and one who had already given evidence of the possession of exceptional knowledge and ability, not only in the department of neurology, but in the whole field of general medicine.

Resolved, That in the death of Dr. Vought his colleagues lose a friend much esteemed for his excellence as a physician, and still more for his good-fellowship, loyalty, devotion to principle, and nobility of character.

Resolved, That this society, in expressing its appreciation of the high qualities of heart and brain of its departed member, and its feeling of regret at his loss, desires in addition to extend its deep sympathy to his bereaved family.

FREDERICK PETERSON, M.D.,
JOHN W. BRANNAN, M.D., *Committee.*

Microbes on Post-cards.—The latest scare in microbes has been started by Professor Uffelman, of Rostock, who infected a letter with cholera bacilli and put it into a post-bag. When the letter was taken out, 23½ hours later, the bacilli were still alive. Bacilli were also found living on post-cards twenty hours after infection. The micro-organisms were found to die rapidly when placed upon coins. A fly charged with cholera bacilli was afterward placed on some beef. A little later the meat was found to be swarming with bacteria. A finger was infected with cholera bacilli and dried. One hour later the finger was rubbed on some roast meat, and numerous bacilli developed subsequently. The moral of all these experiments is obvious.

Gout.—The habitual eater of meat in liberal quantities has a healthier and a less "gouty" urine than the subject of *régime* that limits the proteids. Let practitioners give their patients plenty of red meat, which is the staple of the food eaten by animals which do not produce uric acid. Keep up their energy with dry champagne or some other wine which contains a minimum of alcohol with a maximum of nerve-stimulating property; and for remedies fall back on iodine, combined with diffusive nerve tonics and stimulants, such as musk (Cullen's sheet anchor), camphor, and the other tried remedies of the older and too much neglected type.—GRANVILLE.

Reviews and Notices of Books.

Diagnosis and Therapeutics of Diseases of the Stomach, according to our Modern Knowledge. By Dr. I. Boas, Specialist for Diseases of the Stomach and Intestines in Berlin. Part II. Special Diagnosis and Therapeutics of the Gastric Disorders. With 8 woodcuts. Leipsic: George Thieme. 1893.

Last year we reviewed the first part of this valuable work, which is now completed by the publication of Part II. This part is divided into chapters dealing with the methods of examination, the diagnosis and differential diagnosis, and therapeutics of acute and chronic gastric catarrh, the etiology and diagnosis of round ulcer, habitual constipation, displacements of the stomach, floating kidney, carcinoma, etc. In the chapter on floating kidney, the mechanical treatment of Thure Brandt is described at some length.

The nervous disorders of the stomach are treated of in detail, and there is also a dietary table arranged for every gastric disorder. The print is clear and large, and the illustrations are very good, a noteworthy point being that they are given from the author's personal observation of patients. The book deserves a place in the library of every physician.

L'Inoculation Préventive contre le Choléra Morbus Asiatique. Par le Dr. J. Ferran, avec la collaboration des Drs. A. Gimeno et I. Pauli. Traduit par le Dr. E. Duhourcan. Paris: Société d'Éditions Scientifiques. 1893.

This is a French translation of the work by Dr. Ferran, describing the method of cholera inoculations first practised by himself during the epidemic occurring in Spain in 1885. The results of these inoculations were given at some length in these columns at the time. The author encountered much opposition both from the medical profession in Spain and other countries and from the Spanish authorities, and the latter finally put an end to any further trials of his method. Now that the experiments of Haffkine in the same direction have met with a more respectful consideration, Dr. Ferran very justly feels that his prior efforts should be known, and that any credit for originality which may be his due should be accorded him. The work treats at some length and in a very intelligible fashion of the microbic theory of infectious diseases and of the questions of infection, immunity, and preventive inoculations, and then takes up the application of these new doctrines to the production of artificial immunity against cholera, concluding with a republication of the statistics on inoculations practised by the author in several villages in Spain, during the epidemic of 1885. The book is a timely and instructive presentation of the modern teachings concerning cholera, and it might be read with profit even by those who are seeking information only, and who are indifferent as to who was the first to practise inoculations, the value of which is, after all, by no means as yet proven.

Fermentation, Infection, and Immunity: a new Theory of these Processes, which Unifies their Primary Causation and places the Explanation of their Phenomena in Chemistry, Biology, and the Dynamics of Molecular Physics. By J. W. McLaughlin, M.D. Austin, Tex.: Eugene von Boeckmann. 1892.

There is an air of freshness and originality about this book that makes it, despite its literary faults, most interesting reading. It is an attempt to explain by a purely mechanical theory the action of bacteria in producing disease. The author first discusses the process of fermentation, and proves, to his own satisfaction at least, that the resulting products are formed from substances previously existing which are disinfected by the dynamic energy or wave impacts of the micro organic ferment. To take vinous fermentation as an example, Dr. McLaughlin assumes that, the sugar and the ferment having the same rate of molecular vibration, the presence of the latter so augments the wave motion in the former that the molecules of the sugar became finally forced asunder, and their component atoms rearrange themselves in new groups so as to form alcohol and water. But alcohol has necessarily a different rate of vibration from the ferment, otherwise it could not have formed, or, if formed, would have been immediately disrupted again; hence it opposes the energy of the ferment, and finally inhibits its action altogether. The influence of pathogenic bacteria upon the albuminoids of the body is precisely similar, the author holds, to that of the ferment upon sugar. And in the same way as alcohol is formed by a rearrangement of the atoms of sugar, so are toxines and toxalbumins formed by a rearrangement of the atoms making up the albuminoid molecules in the animal organism. We cannot go more fully into an exposition of this interesting theory, but can only recommend anyone who takes an interest in the problems of disease and immunity to read the book very carefully. It will repay careful reading—indeed, it demands it; and whether the reader accepts the theory here advanced or not, he cannot but admit its plausibility and admire the ingenuity of the author in working it out so as to explain all the phenomena of infection and immunity. The work is marred somewhat by evidences of careless proof-reading and by a few grammatical slips which tend to confuse the sense. But these are not conspicuous enough to detract materially from the reader's pleasure. There is food for deep thought in what the author says, and the reader will furthermore, unless he be already deeply versed in studies cognate to the subjects here treated, glean much incidental information of a useful kind.

Diet for the Sick. By Miss E. Hibbard, Principal of Nurses' Training-School, Grace Hospital, Detroit, and Mrs. Emma Drant, Matron of Michigan College of Medicine Hospital, Detroit. Detroit, Mich.: The Illustrated Medical Journal Co. 1893.

This is a convenient little manual containing directions for the preparation of various dishes for the sick. Diet tables compiled from the works of recognized authorities have been added, and there is also a chapter of "don'ts" for nurses.

Report of General William W. Averell, U. S. Army, Assistant Inspector-General, N.H.D.V.S., to General William B. Franklin, President of the Board of Managers of Inspection of Branches of the National Home for Disabled Volunteer Soldiers and Soldiers' Homes in States. Washington: Government Printing Office. 1893.

This is a report of an inspection of all the Soldiers' Homes in the United States, made during the year 1892. It contains much practical information on various subjects and also some statistics of less value. The old soldiers seem to be pretty generally given to drink, if one may judge from the extensive trials of the Keeley cure that were made in the different branches of the Home.

Fifteenth Annual Report of State Board of Health of Connecticut. New Haven: Tuttle, Morehouse & Taylor. 8vo, pp. 194. 1893.

This report is for the seven months ending June 30, 1892, and is unusually replete with interesting sanitary material. The health of the State has been reasonably good save for the influence of the grip epidemic, which during the season which the report covers, has notably increased the mortality.

Operation Blank. Prepared by W. W. Keen, M.D., Professor of Principles of Surgery in Jefferson Medical College. Philadelphia: W. R. Saunders. 1893.

These operation blanks will serve a useful purpose for the surgeon in reminding him of the details of preparation for the patient and the room, as well as for the instruments, dressings, and antiseptics needed.

Society Reports.

AMERICAN DERMATOLOGICAL ASSOCIATION.

Abstract of the Proceedings of the Seventeenth Annual Meeting, held in Milwaukee, Wis., September 5 and 6, 1893.

MORNING SESSION—FIRST DAY, TUESDAY, SEPTEMBER 5TH.

THE Association met in the club-room of the Pfister House, and was called to order by the President, DR. GEORGE HENRY FOX, of New York, at 9.30 A.M.

Cosmetics, by DR. R. B. MORISON, of Baltimore, Md., was the first paper read. The author said that cosmetics, in a general way, may be divided into two classes, namely, those which are irritating, and those which are soothing. For instance, if we wish to remove freckles or warts, a stronger application must be made than if we simply prescribe for a redness following an acne or an eczema. It is invariably his custom to teach the patient, either through himself or his assistant, how to apply local remedies. Salves, plasters, lotions, and caustics are so often misapplied that experience had taught him to have an application, from which one hoped to get the most good, made by skilled hands to begin with. He finds that nothing suits his patients better for the removal of freckles than the following solution:

℞.	Corrosive sublimate	grs. vij.
	Distilled water	ʒ vj.
	Spirits camphor	ʒ ss.
	Rose water	ʒ v.

Three or four thicknesses of linen, cut to cover the seat of freckles, are moistened with the solution, and placed upon the face at night until they dry, when they are taken off. Whatever remains on the skin is left there till morning, and then washed off. After a few nights' application the face becomes red, and the epidermis begins to peel off in fine scales. Then an ointment is used night and morning, the application being made by gently rubbing it over the face, with a clean finger, for five minutes at a time.

In the removal of superfluous hairs the author has given up electrolysis. The results which he had had himself, and those which he had seen of others, have not been sufficiently good to warrant its continuance. He finds that the proper application of a good depilatory answers the purpose much better. There are many women who wish to get rid of the white lanugo down on their faces, upon whom it seems that electricity cannot be used for fear of stimulating the growth of the surrounding hair, and the appearance of permanent scars. If a preparation of yellow sulphate of arsenic and quicklime, of equal parts, made into a paste with hot water, be allowed to dry on the hairy skin it removes the hair for ten to twenty days, and sometimes permanently. On the other hand, nothing seems to take the place of electrolysis where there are a few strong hairs growing from moles, in the removal of moles themselves, in angioma, or in permanent small red spots.

For the removal of warts the author prescribes the following:

℞.	Hydrarg. bichlor.	grs. v.
	Ac. salicyl.	ʒ j.
	Collodion	ʒ j.

He sometimes increases the bichloride of mercury to thirty grains in the same amount of collodion, if the milder application does not answer. It is applied every day once, the upper crust of the previous application being removed before a fresh one is made Four such applications generally soften the wart to such a degree that gentle traction removes it painlessly, the further dressing being any simple ointment.

The author had obtained excellent results in cases of acne by the use of the galvanic current.

A Case of Rhinoscleroma.—DR. GEORGE T. JACKSON, of New York, read a paper with this title, in which he said that in October, 1892, he had the pleasure of presenting to his class, at the Woman's Medical College of the New York Infirmary, a case of rhinoscleroma. There have been only three cases of this disease reported by the members of the American Dermatological Association since its foundation, in 1877. The patient, a woman, fifty-four years of age, was born in Hungary. The disease began sixteen years ago, as a slight thickening of the upper lip to the left of, and just under, the septum nasi. Since then it has grown slowly and without pain. During the past four years it has increased in size more rapidly than during the preceding twelve years. At present it appears as a hard, well defined, elevated, old ivory-colored mass, located upon the upper lip, beginning at a point a little to the right of the middle line and occupying nearly the whole of the left side of the lip. It runs up upon the left side of the septum nasi to a slight extent. It is slightly lobulated, so that it has an uneven surface, and shows a number of dilated blood vessels running over it, and a number of white points apparently representing plugged-up and dilated follicles. There is no history of syphilis, nor does it look like a syphilitic growth. There is no sign of ulceration nor tendency to break down. She had been previously under the care of Dr. Charles W. Allen, of New York, who had cut out a small piece of the growth, and this had been examined microscopically by Dr. Lustgarten for the bacilli discovered by Frisch, with negative results, on account of the meagreness of the material. Nevertheless there was no doubt as to the diagnosis. The disease is a very rare one, and most of the cases have been reported from Austria and Southern Russia. Only about one hundred cases have been reported altogether.

No satisfactory treatment of the disease has been found. The best results so far reported have been attained by the use of salicylic acid injected into the tumor daily, a one per cent. solution of the acid or a two per cent. solution of salicylate of soda being used; while ten grains of the acid were administered by the mouth three times daily.

A Case of Circumscribed Scleroderma (Morphœa).—This was the title of a paper read by DR. W. T. CORLETT, of Cleveland, O. Mary M——, aged ten, an intelligent-looking girl, well nourished, although slightly pale, presented herself with variously sized and colored lesions on the left upper extremity. These were of two years' duration. The lesions were located on the extensor surfaces, the most typical lesion being situated in the middle third of the forearm. This was of oblong shape, four inches in length and two inches in width. It was slightly contracted, lessening somewhat the circumference of the forearm, and was somewhat depressed, resembling cicatricial tissue. The lesion presented a yellowish-brown central area, with a slightly uneven surface, slightly indurated and non-adherent. No anæsthesia. Hairs were absent. Outside the central zone was a bluish white area surrounded by a lilac pink border merging into normal skin. Veins about the lesion were very prominent. A second spot had appeared, one year after the first, on the back of the hand, the characteristics of which were similar to the preceding. During the four months prior to her first visit to Dr. Corlet, seven other spots appeared on the arm and one on the shoulder. These were smaller than the original. Sharp pains were now complained of, extending from the shoulder to the hand. These were aggravated by writing, but lasted only a few days. Some itching around the margin of the lesions, and occasionally frontal headache, were complained of. There was tenderness over the upper dorsal and lower cervical vertebræ; no motor or sensory impairment anywhere, nor were there any other evidences of cord disease. There was no history which might possibly explain the lesion excepting a fall upon the back at the age of five years. No history of nervous or hereditary disease of any kind in the family. The doctor considered the case as a perfect

type of morphœa originally, but at the present time the case presents a picture of the atrophic stage of scleroderma.

The points of interest are: 1. The changes of clinical form through which the disease has passed. 2. The predominance of the neurotic element, which is so often well marked in morphœa, and which points to the spinal cord as the most probable seat of the disturbance. 3. The confusion of nomenclature of morphœa and its relation to scleroderma is of some interest. Modern treatises on dermatology by American authors are in the main inclined to consider morphœa and scleroderma as distinct affections, while European authorities are rather inclined to the opposite view.

The author has not attempted to advance any original suggestions regarding treatment, contenting himself with the clinical presentation of the case.

A Case of Tuberculosis of the Skin Simulating Lupus Erythematosus.—Dr. W. A. Hardaway, of St. Louis, Mo., read the paper. The patient was a pharmacist, twenty-eight years of age, previous health good, family history good, and no history of tubercle. Tall and spare, and of sallow complexion, yet he is a man of great endurance. In May, 1892, he noticed on his left malar region a small yellowish elevation the size of a pinhead. This was supposed to be a flesh-worm, and was squeezed, blood only being thereby obtained. The lesion gradually enlarged peripherally, becoming hard and red. No subjective phenomena. He came under Dr. Hardaway's care in June, 1892, the lesion being now as large as a dime, presenting an atrophic whitish centre surrounded by a slightly raised infiltrated border of a dull red color. The lesion was anæsthetic, a characteristic which has been noticed in tubercular syphilides. The anæsthesia was temporary. In a short time the patient passed from under observation and was gone for a month, during which time he was thoroughly treated for syphilis by another physician. The treatment simply aggravated the general and local conditions.

September 3, 1892, the original lesion was the size of a half-dollar, not raised from the surface, and moderately infiltrated. The centre is still atrophic, and the same narrow, dull, red line presents at the borders. In a few weeks several small acniform pustules appeared on the right temple, side of the nose, and inferior angle of the right eye. Others presented on the end of the nose, right ala, and left cheek. These lesions were not painful or itchy. Each lesion was surrounded by a red areola, which subsequently extended and became infiltrated, crusts forming over the centres of the lesions. The crusts were fatty or sebaceous in character, and with a dull red surface beneath were suggestive of lupus erythematosus. As the borders of the lesions extended the centres cicatricized, presenting the same dirty yellow appearance of the original patch.

December 9th, thiosinamine was given hypodermically at 12 M., and the patient stated that about 7 P M. the patches became hot and red, remaining so for an hour or two. Other injections of the drug were subsequently given, but without effect.

December 22d, the lesion in the right eye had become as large as a quarter of a dollar. Electrolysis had been tried on the spot on the left temple, but it was still spreading. A new spot was now found on the chest, beginning like an acne papule, which became pustulated and finally scaly. This went through the same metamorphosis as the previous lesions, the elevated red border extending until the lesion was as large as a pea, when it was thoroughly destroyed by electrolysis.

Early in January a small piece of skin was excised from the lesion on the right temple and examined microscopically. Electrolysis was tried upon the other lesions with an apparent cure, followed by a relapse after a few months, manifesting itself first by the formation of a scale in the centre of the scar. Electrolysis was persisted in as fast as the spots appeared, and with apparent success.

In March a small patch similar to the others appeared upon the scalp; this is now the size of a dime. The tendency to peripheral extension throughout has been a marked feature in this case. The whole nose finally became involved, and became a continuous lesion of partly red and partly cicatrized integument, presenting a striking likeness to some forms of lupus erythematosus. Dr. Hardaway thought that this resemblance would have been more striking if the patches on the side of the face had been allowed to coalesce instead of being destroyed by electrolysis.

At no time could nodules of lupus vulgaris be demonstrated, nor were the sebaceous plugs of lupus erythematosus seen at any time. The patient's general health has continued so poor that at one time general tuberculosis was considered imminent. A trip to Colorado brought about great improvement. At last accounts the disease was apparently quiescent, the patient's general health good, and no lesions of the lungs and larynx have been detected.

Dr. C. Heitzmann reports, after microscopical examination of the excised piece of skin, that a moderate number of tubercle bacilli were found. A large number of inflammatory corpuscles were also detected displacing the fibrous connective tissue. Nests of inflammatory corpuscles were seen in the arrangement characteristic of tuberculosis. The diagnosis was local tuberculosis of the skin, which was entirely in accord with the clinical diagnosis.

Lupus Erythematosus as an Imitator of Various Forms of Dermatitis.—Dr. H. R. Crocker, of London, England, read a paper on this subject. The author said that lupus erythematosus as an imitator of various forms of simple dermatitis was a formidable rival of syphilis itself. It was to this aspect of the disease that he desired to direct attention by relating some cases and showing drawings which illustrated the points he wished to place before the Association.

The first drawing was an instance of a lupus imitating erythema tuberculatum. The patient was twenty-seven years of age. The lesions commenced on the right cheek. There was only one spot for the first two years, then others formed on the side of the nose, and they then became scattered irregularly over the face, but, with the exception of a hempseed-sized nodule on the left ear, there were none anywhere else. The lobes of both ears were atrophied looking, but the patient said there had never been any lesions on them. All the lesions were exactly like an erythema tuberculatum, varying from a hempseed to half an inch in diameter, quite smooth except one on the side of the nose which was scaly. They were of a uniform purplish red, except one, which was whiter in the centre.

Case 2 showed an advanced condition of the disease, which began in a similar form to Case 1.

Case 3 was one of lupus erythematosus like erythema papulatum. The patient, aged forty-two, was a cab-driver. Two years previously he had some rash on the cheeks which lasted only a month, and it was not until a year ago that the present eruption began on the sides of the cheek, and has gradually extended until it reached its present condition. The eruption when seen occupied the whole face below the eyebrows, the orbits themselves, and the lower lip escaping, but the chin, except in the centre, was affected. On the left side it extended above the brow, but below the orbits it was remarkably symmetrical. The most recent lesions were on the lower part of the side of the face and below the jaw. In these positions they were the form of erythematosus, slightly raised disks from a half to a quarter of an inch in diameter; the most recent were of quite smooth and slightly convex, the larger ones were not prominent in the centre and but slightly scaly.

Case 4 was like diffuse erythema, the patient being a lady, forty-three years of age. The disease had commenced three years previously as a small red spot on the side of the nose and had spread continuously; the whole nose intensely reddened and slightly scaly, the skin

thickened and infiltrated, but the orifices of the sebaceous glands were not patent or plugged.

Another disease which lupus erythematosus imitates is psoriasis, and the author reported a case in point. A rarer imitation is that of lichen planus, of which the author had seen only two cases.

Dr. Crocker also reported a case of lupus erythematosus nodulatum. He had met with three or four other cases of this, but not with so many distinct foci of disease. In two cases there was only a single nodule in each. He also remembers a case in which there were even more foci of disease, in a patient of the late Dr. Tilbury Fox. Cavafy also showed a case at the Dermatological Society of London, in 1892, but Dr. Crocker was not aware of any other cases having been recorded.

The Treatment of Pruritus.—Dr. E. B. Bronson, of New York, followed with a paper on this subject. The author said that in the management of pruritus essentialis, as of any other disease, the first consideration should be directed to what caused the trouble. The adoption of measures tending to remove any accidental conditions or influences through which pruritus might be occasioned is important. Such causes include, besides various local sources of irritation, certain remote or general diseases, and furnish the *indicatio causalis* in its more limited sense. This, however, states the scope of the problem only partially. What is of more importance is to establish principles of treatment fitted to those more special and more essential causes that constitute the necessary conditions of the disease, and whence we derive the *indicatio morbi*. These causes are traced under etiology, and it is they which must afford the only intelligent basis for the therapeutics of pruritus.

The chief underlying condition in pruritus is hyperæsthesia, whether in its common significance of an excessive irritability of the sensory nerves, or in the sense of an excess or engorgement of sensation. The prime indications, then, are to allay irritability and to divert or annul the excess of nervous excitement. Measures to remove local excitants, include, first of all, such as directly tend to prevent scratching. To admonish the patient to refrain from this is usually of little avail. Restraint may be possible during waking hours, but at night, when the trouble is always at its worst, and especially during the state of somnolence midway between sleeping and waking, no power can prevent it. It can only be avoided by first mitigating the lesion through the aid of anti-pruritics. Sedatives when used internally are apt to be disappointing. The degree of general sedation that is required to affect the nerves of the skin in so intense a disturbance as pruritus often is, affords a sufficient reason why this method of treatment is usually objectionable. Further than this, the depressing and atonic after-effect on the nervous system tends to exaggerate the general hyperæsthesia, which is already essentially an atonic condition, and thereby increases the tendency to itching. Especially objectionable are most of the narcotics. The bromides, on the other hand, are often indispensable and may be required in liberal doses. It is important to avoid the enervating effects of loss of sleep, and for this purpose sulphonal or some other hypnotic is occasionally needed. In connection with this, two internal remedies, which have been especially recommended by Bulkley, are worthy of mention, and they are cannabis indica and gelsemium. The former is known to be a cutaneous anæsthetic as well as an analgesic, and by virtue of the former quality should be useful in pruritus.

Carbolic acid is the most reliable and most generally useful anti-pruritic which dermatologists possess. It was well named by Unna "the opium of the skin."

The following "anti-pruritic oil" has been much employed by the author for years, both in a local and so-called universal form of the disease, with no more untoward results than now and then a trifling dermatitis, when through oversight the patient has been allowed to make the applications too frequently, or has continued them too long. The formula is:

℞. Carbolic acid ..... ʒ i–ij.
Liquor potass ..... ʒ j.
Ol. lini ..... ʒ j.
Sig.: Shake before using.

To correct the disagreeable odor of the linseed-oil a drop or two of the oil of bergamot may be added. Salicylic acid and salol, though less energetic in their effects, act similarly to the carbolic acid. Thymol is also an admirable anti-pruritic, but on account of its irritating effect cannot be used when the skin is sensitive.

The author then dwelt on sensory stimulants, substitutive irritants, alteratives of cutaneous nutrition, and motor depressants. In pruritus hiemalis an all-important measure of treatment is protection against cold. The sole cause of winter pruritus, aside from a special predisposing hyperæsthesia, is lowered temperature.

Angiokeratoma.—Dr. Joseph Zeisler, of Chicago, Ill., read the paper and reported the following case: The patient was a German, fifty-three years of age, butcher by occupation. Had never had any severe illness, but had malaria once. Present illness began somewhat gradually about four years ago with red spots and verrucæ on the skin of different parts of the body. He was under medical treatment, and says he improved for a time. He states that some of the red spots gradually disappeared at times, but returned, and new ones arose in different localities. During all this period his general health had not suffered in the least. No anorexia, headaches, nor any other complaint. There is no pain or itching in the skin lesions. Patches of vitiligo of large size are found on the front and sides of the abdomen, and on the right side of the thorax. Some small patches in right axilla. Faint patches on right side of chest, posteriorly, and on the neck. Large patches on the penis and scrotum, and small ones on the inner surface of the thighs. There are some old marks of tinea favus on the scalp. Nævus-like spots and small tumors are scattered over the body as follows: On posterior surface of right ear are two small warts, red in color and vascular; one on posterior aspect of left ear. On the ulnar surfaces of both forearms, beginning over the olecranon, are found red, nævus like patches of irregular contour, and smaller isolated ones in the form of small pedunculated tumors. The patches vary in size from three or four inches in circumference to the size of a dime. They are red in color, vascular, and slightly raised above surface of surrounding skin. On the right forearm are numerous small tumors, varying in size from minute spots to some the size of a hazel-nut. The larger ones are all pedunculated, firm, and vascular. On the left forearm they are fewer in number. Considerable œdema in the right hand and fingers. Only one or two small warts on the extensor surface. On palmar surface there are some on every finger except the index, and none on the wrist and ball of the thumb. One was removed and found to consist of an outer layer of thickened epidermis surrounding a very vascular centre. Microscopical examination was made by Dr. Zeisler. Some of these tumors sprang out from beneath the fingernails. On the left hand the verrucæ were not so numerous, and inclined more to the small vascular variety, with two exceptions. Large, irregular, red patches were also found over each patella, and a few smaller ones irregularly scattered over anterior aspect of the legs and thighs, also a few smaller ones over the posterior aspect of thighs, and one over the back of each ankle. Two small pedunculated warts were also found on the back of right leg; another with some of the red patches on the nates near the gluteal fold. No patches or tumors were found on abdomen, thorax, or upper part of arms.

The author reported this unusual and interesting case to show that the clinical picture of the disease is evidently not yet quite complete, and hoped that new examples of the disease would arise which would throw more light on the pathology and etiology of the affection.

A Contribution to the Pathology of Acne Variioliformis (Hebra).—Dr. J. A. Fordyce, of New York, read a paper on this subject. He called attention to the

case described by Dr. Bronson and himself, in 1891, under the title of "Acne Varioliformis of the Extremities," which was at that time shown to originate in or about the coil glands. This was identical with cases since reported by Politzer, Dubreuil, and others, under the name of hydradenitis, and should go on record as an example of that affection. While clinically it presented many points of similarity to acne varioliformis (Hebra), its pathological anatomy was quite distinct.

The writer had examined microscopically a number of papules and papulo pustules from two typical cases of the latter disease, and was able to trace its beginning to an inflammation about the middle and upper portions of the hair-follicles and their sebaceous glands, while the coil glands were shown to be outside the inflammatory area. Enormous numbers of staphylococci were found in sections from one of the cases examined, which readily stained with Kuhne's carbolic methyline-blue solution. These organisms were especially numerous about the middle and deeper portions of the hair-follicles and were contained within the external and internal root sheath, in the connective tissue about the coil glands, and in the subcutaneous connective tissue. In considering their number, distribution, and presence in the diseased area before the epidermis was involved, the writer was disposed to consider them a direct influence in producing the lesions. In a secondary infection they would scarcely be found at so early a period in the evolution of the papule.

As a result of his investigations Dr. Fordyce concluded that acne varioliformis (Hebra) was an inflammation of the pilosebaceous system, of microbic origin, leading to destruction of these organs, and that Bazin was correct in naming the disease acne pilaris.

The members of the Association, at the close of Dr. Fordyce's paper, participated in a general discussion on "Pityriasis Rosea and Pemphigus."

Election of Officers. — The following officers were elected: *President*, Dr. Robert B. Morison, of Baltimore, Md.; *Vice-President*, Dr. George T. Jackson, of New York; *Secretary and Treasurer*, Dr. Charles W. Allen, of New York; *Member at Large of the Council*, Dr. J. A. Fordyce, of New York.

On motion, the Association adjourned to meet in Washington, D. C., in connection with the Congress of American Physicians and Surgeons, in May, 1894.

Pan-American Medical Congress.

First Meeting, Held at Washington, D. C., September 5, 6, 7, and 8, 1893.

(Special Report to the MEDICAL RECORD.)

(Continued from p. 445.)

SECTION ON HYGIENE, CLIMATOLOGY, AND DEMOGRAPHY.

ALBERT L. GIHON, M.D., MEDICAL DIRECTOR U. S. N., WASHINGTON, PRESIDENT, IN THE CHAIR; ENGLISH SECRETARY, PETER H. BRYCE, M.D., TORONTO, CANADA; SPANISH SECRETARY, PEDRO JOSÉ SALICRUP, M.D., NEW YORK CITY.

SECOND DAY, WEDNESDAY, SEPTEMBER 6TH—AFTERNOON SESSION.

Sanitary Work in St. Louis.—DR. HOMANS, of St. Louis, Mo., opened the afternoon session by an able and instructive paper on "Sanitary Work and Precautions in St. Louis." He described the workings of its Board of Health, of which he is President. It is composed of physicians, public vaccinators, and corps of sanitary inspectors, chemists, etc. There is in addition a disinfecting corps. All questions bearing on public health, as affecting the city of St. Louis, were discussed by Dr. Homans, at length — markets, slaughter-houses, bad food, impure water, smoke, dust, etc. St. Louis, in common with other cities, has had her knotty questions, but they are being solved. A novel feature was the photographing of nuisances. The practice has been found valuable for purposes of record and as evidence in court, where actions have been brought against the Board. These they used for justification of the Board's action. The Board's chemist was kept busy analyzing drinking-water, foodstuffs, etc. All contaminated wells were closed.

The "pin-and-map" system was used for locating unhealthy spots and houses, and was found useful and very effective.

General and Efficacious International Maritime Policy.—DR. EDUARDO LICEAGA, of the City of Mexico, President of the Supreme Council of Health of Mexico, followed. His theme was, "The General Bases which should Govern the Continent of America in Promulgating a General and Efficacious International Maritime Policy." After some introductory remarks he referred to the incessant progress of science, spoke of the United States as the representative of science, in the "Three Americas," and then dealt with the subject of his paper, the question of quarantine against disease and disease-carriers; the necessary detention of ships from infected ports; such ships he divided into three classes—immune, suspected, infected. The paper was read in Spanish. It was an able one, indorsing the views of the Dresden Congress on all matters pertaining to quarantine, and recommended that they should be applied on this continent. In short, he outlined an international quarantine for mutual protection.

Pneumonia. — DR. ORRAÑOS, of San Luis Potosi, Mexico, likewise a member of the Supreme Council of Health of Mexico, followed in a paper in Spanish. His subject was "Pneumonia: Its Dangers as an Infectious Disease." He referred to the three climates of Mexico—Tierra Fria, Templado, Caliente—or its cold, temperate, and coast or tropical climates. He dwelt on the distribution of pneumonia from Zacatecas in its highlands to Campeachy on the Gulf of Mexico. March and April, at the close of the Mexican winter, gave the heaviest death-rate. In some places it was more fatal than others. He cited much of general interest regarding infected houses, citing case after case in the same house, visitors to pneumonics having contracted the disease and taken it to others. In other words, its propagation by individuals and air. Malaria and pneumonia had a *rôle* frequently observed in Mexico. He deems the disease highly infectious. He cited a case of a man who died of pneumonia. A month later his clothing was sent to a family. Soon after two children in that house were ill with the disease. Another illustration was that of a woman who nursed a pneumonic—sleeping in the same room; she likewise contracted the disease.

An examination of records of cases of pneumonia in given localities had proven very instructive. In two years thirty-one cases had been traced to infected houses, case after case in the same house. The germ of the disease, the pneumococcus, he deemed almost indestructible in Mexico.

DR. ORRAÑOS'S paper was timely, and threw new light on the careful and painstaking work of medical men and sanitarians in Mexico.

Then followed a lengthy discussion on quarantine; over fifty experts and sanitarians were present. A great variety of views were expressed, when the following was offered, moved by Dr. Rauch, of Chicago, seconded by Dr. Flick, of Philadelphia:

"*Resolved*, That in the judgment of the Section of Hygiene, Climatology, and Demography of the Pan-American Medical Congress, immigration should be suspended, from a sanitary and economic stand-point, from all countries and ports in which cholera prevails, until the present pandemic is over."

DR. LEE, of Philadelphia, spoke in favor of it. DR. STEWART, of Baltimore, thought it too sweeping. DR. FLICK maintained the principle. DR. SHAKESPEARE, of Philadelphia, spoke in favor of the motion, dwelling on the conflicting interests of commerce and immigration.

He referred to the "habitual evasion" of agents of steamship lines and the habits of concealment practised by shipmasters. Measures must be adopted for general protection.

Dr. Cyrus Edson, Board of Health of New York City, was cordially in favor of stopping immigration from infected ports. He did not believe it possible to maintain a successful cholera quarantine. He deems the common house-fly an active agent in spreading the disease. Between the arrival of an infected ship at a port and the appearance of the disease a single day may suffice.

Dr. Gihon, the President of the Section, named a committee of three to draft a resolution. He named Drs. Shakespeare, Lee, and Cyrus Edson. They reported back as follows:

"*Resolved*, That it is the sense of this section that, in view of the prevalence of Asiatic cholera in Europe at the present time, and the constantly increasing number of *foci* of infection, immigration from European countries in which cholera exists should be temporarily suspended, as this action affords, in our opinion, the only certain means of averting a threatened invasion by the disease of the countries of the American continent.

"Be it further *Resolved*, That the resolution be reported to the General Session of the Pan-American Medical Congress, with a request for its adoption and speedy transmission to the executives of the several countries officially represented therein."

Dr. Otis, of California, moved, it was seconded and carried, that a recommendation be sent to Congress requesting a reprint of Dr. Shakespeare's valuable book, entitled "Report on Cholera in Europe and India," and that copies be distributed to all the members of the Pan-American Medical Congress.

Need of Research in Preventive Medicine.—Dr. J. M. Postle, of Illinois, read a paper on this subject. He said, *inter alia*, that the country was threatened by epidemics that came to our shores from foreign lands. He referred to the etiology of disease and deemed "an ounce of prevention better than a pound of cure." Sanitary science was deeply indebted to Lister, Virchow, Pasteur, and others. Jenner's invaluable discovery was mentioned. He said: "If vaccination is protection against one disease, why not vaccination against many diseases?" Bacilli-ptomaïnes and their absorption were fully discussed. He wished to see America in the front rank of medical science and preventive medicine. In other words, "first in all that advances the welfare of mankind."

"The School in Relation to the Spread of Diphtheria."—Dr. Peter H. Bryce, of the Provincial Board of Health, of Toronto, Canada, read the paper. His investigations show that twenty-five per cent. of all cases occur between the first and the tenth year, and that fifty-five per cent. of all cases occurred among the school population of Ontario. It causes a heavy mortality in that province. The highly infectious character of the disease was referred to the fondness of its germ for damp and unhealthy homes. The germ of diphtheria does not thrive in light and well-ventilated rooms. In such it becomes inert in two or three weeks. Warmth increases the number of germs. Inoculation is possible through any mucous surface.

Dr. Farr, when Registrar-General of England, as a result of many years of study and observation, could predict the death-rate for a given locality—either by the acre or mile—if its population was given him, the rule being, the denser the population the greater the death-rate. It was known as "Dr. Farr's Law of Density."

Schools, their impure air, overheating, etc., were discussed, and as such were shown to be dangerous. His conclusions are: 1. Diphtheria in houses is an intensely infectious disease. 2. It may be mild in some patients and they may give the disease to others, in whom it will be of extreme virulence. 3. It is influenced by atmospheric conditions. 4. Diphtheria is particularly prone to attack children under ten years of age. 5. It is a disease caused by a germ—the germ has a capacity for prolonged existence. 6. Free air kills them. 7. They are capable of producing epidemics through the medium of public water supplies. 8. Epidemics are not produced except by direct infection by persons and children visiting infected houses, etc.

Diphtheria has no special habitat. A cold climate favors the disease, as houses in winter must be kept closed and warm.

The section then adjourned until 10 A.M. the next morning.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE CHOLERA INVASION—OFFICIAL REPORTS—FRESH CASES—LONDON COUNTY COUNCIL—BRITISH SCIENCE ASSOCIATION—PROFESSOR SANDERSON'S ADDRESS—RELATION OF BIOLOGY TO EXACT SCIENCES—SECTIONS OF BIOLOGY, CHEMISTRY, AND ANTHROPOLOGY—DEATH OF THE MEDICAL CENTENARIAN—DEATH OF SURGEON-MAJOR PARKE—LONDON WATER SUPPLY—THE ROYAL COMMISSION REPORT—QUALITY—QUANTITY—COUNTY COUNCIL'S EXPLORATION—DEATH OF "CLAY OF MANCHESTER," OR THE "FATHER OF OVARIOTOMY"—BRISTOWE MEDAL—REGISTRATION OF MIDWIVES—CHOLERA—JENNER—EXHIBITION.

London, September 16, 1893.

Although in some quarters there was a disposition to make light of the invasion of cholera which I reported in my last, there can be no doubt that the few cases that have occurred are now causing some anxiety. On Thursday the Local Government Board issued an official statement showing which were cases of the Asiatic type, and that some others were not of that character. Dr. Thorne summed up his statement by the remark that "the history of the more recent occurrences, and their isolated character, may be regarded as reassuring respecting the immediate future." Last evening a further official statement was issued by Dr. Thorne, to the effect that no further deaths had occurred from the disease up to midday at Hull, Grimsby, or Cleethorpes. Only one fresh attack occurred at Hull, and three at Grimsby. Some reported attacks at Bingley turn out not to have been cholera at all. The outbreak at Ashbourne affected fifteen persons, with nine deaths, and all had been using a contaminated well, to which the symptoms are attributed. "Stringent measures are being adopted, and no fresh attack has been reported." I may add that in several localities sporadic cases of a suspicious character have occurred and caused alarm. All are being carefully investigated.

The London County Council has taken an important step. Their medical officer has been authorized to obtain a bacteriological report from Dr. Klein in all cases of suspected cholera in the county. A letter has accordingly been sent to each medical officer of health, informing him of this and inviting him to send early information of suspected cases. The Local Government Board is a party to this arrangement, and therefore no hitch is likely to occur, and it will certainly be a relief to medical officers of health to be able to obtain, without delay, an expert opinion on a suspected case. It is still generally thought in professional circles that we may escape a serious epidemic.

This week the British Association for the Advancement of Science has held its sixty-third annual meeting, the town chosen for the gathering being Nottingham, and the president, Dr. Burdon-Sanderson, the professor of physiology at Oxford. This association is usually attended by a considerable number of scientists, as well as by those who cultivate science in a dilettante sort of way. Naturally medical men hold their own at the congress, and an eminent biologist as president is to us an attraction.

The proceedings commenced on Wednesday, with the meeting of the general committee, the appointment of sectional officers, and other formal business. In the evening Dr. Sanderson delivered his presidential address. He dwelt for a moment on the influence exercised by the association, and lamented that England did not take her part in the full development of natural knowledge. He then took up the subject of biology, which he had chosen for his address. The word biology, so familiar as comprising the sum of the knowledge acquired concerning living nature, did not come into use until the present century, being first employed by Treviranus, whose conception of the science still expresses its scope. The origin of life the president pronounced to be a "riddle that lies outside our scope," though he admitted no seriously minded person doubted that organized nature, as we observe it, has become what it is by a gradual perfecting process or advancement. The founders of modern physiology are Müller, Brücke, DuBois-Reymond, Helmholtz, and Bernard. The great advance in the middle of our century was due to a change of method, not of doctrine. Analyzing a vital process so as to bring its components into relation with physical or chemical standards, is the only mode of investigation that promises satisfactory results. Organism is a fact, said Dr. Sanderson, which encounters the biologist at every step. In referring it to a principle, such as adaptation, we do not explain it, and no explanation will be attainable until the conditions of its coming into existence can be subjected to experimental investigation, so as to correlate them with those of processes in the non-living world. Physiology can never become a mere branch of applied physics or chemistry, although there are parts of physiology in which we may directly apply the principles of these sciences. There is, then, no doubt of the advantages which physiology derives from the exact sciences, though they in turn can hardly benefit to the same extent from our science. Nevertheless there are some points in respect of which physiology has contributed to the advance of chemistry and physics, and there are methods, both physical and chemical, which were first devised for physiological purposes.

The president's address was listened to with great attention, and the usual vote of thanks heartily given. On Thursday the eight sections set to work in earnest, the president of each opening its proceedings with an address. After Dr. Sanderson's address medical members would naturally compare it with what passed in the sections of biology and chemistry. In the former Canon Tristram was to have presided, but was absent, and his address was read for him by Sir W. Flower. The canon discussed biology from the point of view of an old-world naturalist, and warned the observer of facts not to become a mere materialist. The poetic faculty, the imaginative, the emotional, the spiritual, all went to make up the man, and if any of these were missing the man must be incomplete. He said the life of that great master, Darwin, showed the danger of concentration upon one side only of nature, and illustrated the law that the spiritual faculty lives or dies by exercise or the want of it, just as does the bodily. Professor Emerson Reynolds presided in the chemical section, and while fairly noticing what had been done in the chemical education of medical men, put in a plea for better instruction in experimental methods. Dr. Robert Munro presided over the anthropological section, and claimed that his science embraced all the materials bearing on the origin and history of mankind. He traversed the hopothesis of natural selection, and urged that many of the existing tribes of savages are probably more degenerate than their forefathers. There must be truth in the tradition of the fall of man. The progress of humanity was in the main steady, but slow. The civilized world of our times had brought about a code of social and moral laws, obedience to which was virtue, and in the words of a profound thinker, involved a course of conduct in all respects opposed to the struggle for existence. In place of ruthless self-assertion it demanded self-restraint; in place of thrusting aside and trampling down competitors, it required a person not merely to respect but to help his fellows. Its influence was directed not so much to the survival of the fittest as to the fitting of as many as possible to survive. It repudiated the gladiatorial theory of existence.

Our medical centenarian has fallen a victim to influenza complicated by embolism. He was taking his usual constitutional only four days before his death. Dr. Severin Wielobycki was born January 8, 1793, and so lived one hundred years and eight months. He was a Pole, fought for his country's freedom as a cavalry officer in thirty-six engagements, but had to flee when Poland fell. In 1841 he took his M.D. at Edinburgh, and afterward practised in Nova Scotia, England, and Scotland. He retired twenty-eight years ago, and has lived in London or its suburbs since. In January last his medical friends joined in his centenary ovation and rejoiced to find him so hale, although he had previously had two attacks of influenza.

Surgeon-Major Parke, of African fame, died suddenly on the 10th inst., when on a visit to the Duke of St. Albans, in Scotland. His priceless services in the expedition for the relief of Emin Pasha were enthusiastically acknowledged by Mr. Stanley, and are familiar to all who know anything about African exploration. He was received with honor by the public as well as by his profession when he returned home. But the government of the day gave him no mark of honor—perhaps because he was only a doctor and partisans of politicians were clamorous, while Parke's modesty and sterling worth would be satisfied with the consciousness of duty well done, lives saved, dangers and hardships bravely endured. His "Experiences in Equatorial Africa," and his "Guide to Health in Africa," contain much interesting and valuable matter.

LONDON, September 23, 1893.

The Royal Commission on the London Water Supply have presented to Parliament their report, which is much more favorable than has been generally expected, both as to quantity and quality. The commission was composed of men of high scientific authority and will naturally carry great weight. In this report, though pessimists have been predicting a water famine at an early date, we are calmly assured that we need not go beyond our own watershed to obtain an abundant supply for all our needs, and that if the population doubles itself in the next thirty or forty years there would be enough and to spare, with proper management. The commissioners estimate that by supplementing the river water from the chalk which underlies London, a daily quantum of thirty-five gallons a head for twelve million inhabitants could be obtained, and that is the population for which it is estimated provision will be required in 1931. In times of drought the supply runs short, but in rainy seasons floods cause much mischief. To equalize the supply it is proposed to construct at different points of the river's course enormous reservoirs in which to store flood water and let the impurities subside. Thus the water passing into the filters would not be turbid—subsidence having previously taken place. In regard to quality, the commissioners propose that the conservancy should be entrusted with much larger powers and enabled not only to prevent pollution of the river itself but to deal with its tributaries. This is a most important point, for the pollution of these tributaries is a constant source of danger. The commissioners accept the terrible lesson of Hamburg and Altona as to the value of filtration, but declare it must be supervised vigilantly to secure its being of the best kind. It is suggested that regulations should be formulated by experts, and their enforcement trusted to the official water examiner, who could be enabled to act instead of merely advise. The expense of this and of more inspectors, it is held, should be defrayed by the companies, and as they make enormous profits by their monoply it seems only just they should be compelled to supply a pure article. They will no doubt rejoice at the report, for they had reason to fear an end of their mo-

nopoly. At the present time the County Council is employing surveyors to explore various localities in order to obtain fresh sources of supply. The tenor of the report of the commissioners will, however, discourage the council and perhaps definitely postpone this proceeding.

The "father of ovariotomy" died on Tuesday the 19th inst. He was nearly ninety-two years of age, having been born December 27, 1801. He was for many years familiarly spoken of as "Clay of Manchester," where he practised for the whole period of his consultant career. When he began that he had had fifteen years' experience of general practice. Charles Clay's first ovariotomy was performed in September, 1842, just fifty-one years ago, and for fifteen years he was almost the only operator. He was overworked and had to take some rest, but in that time he brought the history of his three hundred and ninety-five cases before the Obstetrical Society. It was after this that Spencer Wells went to Manchester to see Charles Clay operate, and (in 1858) began to follow the example. In 1845 Clay removed a fibroid uterus by abdominal incision, anticipating Koeberlé by eighteen years. Charles Clay's career is historical in more senses than one. He wrote many contributions on his special subject for the periodicals. His "Handbook of Obstetric Surgery," with its ninety plates, must be known to many of your readers. He was an amateur geologist, and much interested in numismatics. But it is as the "father of ovariotomy" in England that "Clay of Manchester" will be remembered. He retired from practice years ago, and has been enjoying a green old age with good health and the use of all his faculties. He took great delight in his garden, but he could also travel considerable journeys without difficulty. On the day of his death he went to see a house which he thought of taking, but after returning home an attack of syncope closed a remarkable life.

Nearly £400 has been been raised as a testimonial to Dr. Bristowe, who out of the money has founded and endowed a "Bristowe medal," to be awarded annually for proficiency in pathology to a student of St. Thomas's Hospital.

The Select Committee on the Registration of Midwives has given rise to unusually lively discussions. The evidence offered in some instances has been of rather a startling kind, and those who gave it have been subjected to criticism. Wherever general practitioners meet, the midwives' question in some form is sure to come up. It is very much, if not altogether, a general practitioner's question, and the obstetric consultants can hardly be able to see it in the light it is viewed by the vast majority. A little strong language is therefore not unnatural on the part of those who fear the encroachments of a new order of inferior competitors; but why the consultants should give way to temper in the matter is another question. They are not agreed among themselves, and their controversies are quite as bitter as those of their humbler brethren whose interests are in danger. An obstetrician to a great hospital, who can always rely on the pick of trained nurses, may know very little of the conditions under which an accoucheur has to work in a crowded city slum or a remote village hamlet. The highly placed gentlemen who can command every help might well leave to those concerned the description of other positions, or if determined to interfere might spend one of their vacations as *locum tenens* for one of their overworked brethren, to see for themselves how such practice is carried on.

We have had a daily official report as to cholera during the week, and, throughout, these reports have been favorable. Very few fresh cases at the ports have occurred, and some of the suspected cases have turned out to be not cholera. One supposed London case on being sent to a hospital was found to be strangulated hernia. If we are able to ward off our danger a little longer we may escape this year. But how about next year? The predictions of the epidemiologists have been right in other places—that a recurrence is likely—will it be so with us? The question already occupies attention.

A very interesting collection of relics of Jenner, the originator of vaccination, has been exhibited at Bristol, and it is hoped that London may also have an opportunity of seeing them, and possibly of retaining them permanently.

SPECIALTIES IN MEDICINE AND SURGERY.

To the Editor of the Medical Record.

Sir: Is a specialty in medicine or surgery possible? This is no new question, but one that is being constantly and anxiously asked by the young and old of the medical profession. The longer I live, the more I read and observe, the more convincing become proofs that a specialty in the true sense is not possible, unless we broaden the sphere instead of curtailing it. Take, for instance, the very latest in laryngology and rhinology. "Epilepsy is a frequent result of peripheral irritation." So says one of our best known throat and nose specialists. Again, he tells us that the nose is frequently the seat of sufficient irritation to excite a variety of reflex manifestations. Granting the truth of this doctor's observations, who will gainsay or question that the amount of peripheral irritation at the other openings of the body may not have a most important bearing?

Do we not in chronic diseases need a specialty that requires us to examine all the other openings that may present peripheral irritation? One that will not alone allow us to treat a chronically elongated palate, causing an irritating throat cough, or hypertrophied tonsils, yielding a product of mucous or calcareous matter, thickening the voice, and congesting the fauces, pharynx, etc? One that will not alone allow us to cauterize the turbinates of the nose, thereby curing almost immediately sciatica, headache, and vertigo?

Do we not need a specialty that demands the closest scrutiny of all the organs, no matter from which comes the wail indicative of functional derangement? The tortured, irritated brain, the stuffed nose, the congested kidney, the irritable stomach, the debilitated sexual organs, the failing heart, the clogged liver, the impeded lungs, may all be so many index-fingers pointing to peripheral irritation as the cause.

Is it safe, then, in any form of chronic disease, to say that it originates in and affects only the one organ. Someone has wisely and truly said: "Every local chronic disease has its genealogy, and he who can trace this life-history is a good diagnostician."

Another has equally well said: "An organ is but a part of the general system, and is so intimately connected with every other tissue that it is seldom that a single organ is diseased alone. Every disease is due to an impression made upon the nerve-centres supplying the part, changing its capillary circulation."

Is it in the organ from which the pain begins, in the nerve-centre, or in the organ affected? This is the nut for the specialist to crack. Here comes in the ability of the diagnostician.

That peripheral irritations cause pneumonia, pleuritis, coryza, etc., is true, and a specialist might perhaps treat more successfully; but he must not forget in these cases the central impressions, septic or simple, affecting one nerve-centre primarily, but secondarily affecting another centre, causing a far-away inflammation. A cough and spasm of the larynx may come from papillus on the tongue, or laryngeal spasm from phimosis, or papillæ and pockets in the rectum; hæmorrhoids may also produce it. The general depressing reflex effects of pockets and papillæ of the rectum are, comparatively speaking, unknown to the medical world.

To appreciate reflexes is to be a diagnostician. The great vaso-motor system is always thought of, but we must not forget the sympathetic system. When we realize that the sexual organs carry on their functions by means of nerve-filaments sent to them by the presiding genius of life in the human economy—the great sympathetic—as extensive in their area of influence as the mucous membrane, muscles, and glands that con-

stitute the sexual apparatus, it is not difficult for us to see how a diseased condition affecting any part of this apparatus can, through these nerve-channels, send continuous streams of disturbing influence to any and all parts of the system. A sensitive spot in the throat may produce general neurasthenia; hypertrophy in the nose causes neuralgia, asthma, etc.; and so will rectal troubles.

It has also been said that it is a pathological fact not to be denied, that the irritation of an organ invariably starts at its mouth: and it is communicated from thence to the body of the organ. Thus, a diseased external os uteri will cause inflammation of the neck of the organ, and an irritation of the internal os may set up endometritis and other difficulties that assail the body of that organ; while many troublesome ovarian weaknesses are unquestionably due to the irritation of the uterine orifices of the Fallopian tubes, which travels up and affects the body of the gland.

Again, it has been said that reflex phenomena may completely overshadow exciting causes. I am sure, too many reflex diseases are treated as idiopathic ones. In these cases, when it comes to treatment, the unsound trees are shorn of their foliage and the diseased roots left untouched. The rectum is particularly entitled to careful study and consideration; its anatomical characteristics demand it, for the reason of dissimilarity to other sections of the alimentary canal. The outlet is prone to take on various forms of difficulty that create an infinite variety of symptomatic phenomena. It is in the countless array of symptoms, subjective and objective, of orificial pathology and treatment that are so deeply interesting. Any physician can account for a majority of the chronic diseases and derangements of the pelvic viscera by looking to contiguous organs for the primal point of disturbance. A contracted meatus not of special significance as an entity, reaps its dire consequences upon the prostate, bladder, kidneys, or other structures. If this be so, why not look for reflex trouble from a rectal sphincter that is in an unmitigated state of contraction? The operations of the sympathetic nerves are beyond the control of man. We can nurse and propitiate the cerebro spinal, but the great ganglionic, by day and by night, works independent of us. I have seen many cases of prostatic trouble, irritability of the urinary bladder, of the uterus and ovaries, created solely by a fissure of the anus, or rectal papillæ or pockets with inflamed and infiltrated edges. In conclusion, let me urge the consideration of a specialty that includes at least all the openings of the human body, as peripheral irritations there begin. An irritation of an organ truly starts at its mouth. So let us examine the mouth and throat, then the lungs, not forgetting the heart, and so on through the body to the lower openings; the revelations there to be found are sometimes astounding.

THE MEDICAL PROFESSION AND DISCOVERY OF AMERICA.

To the Editor of the Medical Record.

In the abstract of my paper on "The Part Taken by the Medical Profession in the Discovery of America," read by me before the Section on General Medicine of the Pan-American Medical Congress, published in the Medical Record a week ago last Saturday, two errors are made, one by commission and the other by omission. The first one is saying the "intentions" of Avicenna, instead of the "opinion" of Avicenna, expressed in his work entitled "De Complexionibus." The error by omission consists in not mentioning the very important fact that, although it is proved beyond doubt that no priest accompanied Columbus in his first voyage, there were two representatives of our profession among his followers, two ship surgeons, or *fisicos*, one named Maestre Alonso, on board the caraval Niña, and the other called Maestre Juan, on the Pinta. The first one was the one who paid with his life his professional devotion, and not Dr. Chanca, as quoted in the abstract made by Dr. Bishop for your journal. Maestre Alonzo was one of the thirty eight men left by Columbus in the fortress "La Navidad," who were all massacred by the native Indians before the return of the discoverer on his second voyage.

Very truly yours,

A. M. Fernandez Ybarra, M.D.

94 West Tenth Street, New York, October 2, 1893.

New Instruments.

A MODIFIED PARKINSON ETHER INHALER.

By W. K. Kubin, M.D.,

interne German Hospital, New York.

The Parkinson Ether Inhaler described in the *Sacramento Medical Times*, March, 1887, has been in use at the German Hospital of New York for more than a year. In our hands it has been found preferable to all other inhalers that have been tried, although several deficiencies have been observed which I have endeavored to correct.

In the first place: We have found that in almost all cases the patient will not tolerate at the outset as great a concentration of ether vapor as results from pouring on the sponge thirty grammes at once, as is recommended by Dr. Parkinson. The patient will struggle, hold his breath, sputter, and in every way give evidence of alarm and dread, thereby counteracting all previous reassurances which may have been made to him. Furthermore, the patient invariably, in his struggles or in his efforts to cry out, will open his mouth and inspire a large amount of cold concentrated ether vapor, which, as is well known, causes troublesome cough and an excessive secretion of mucus.

To avoid these difficulties we have found it necessary to begin the use of the anæsthetic gradually, and to add at frequent intervals a fresh supply of ether. Since the Parkinson inhaler possesses no way of feeding the sponge except through the mouth opening, it is necessary at each addition of ether to remove the mask from the face. During this interval the patient takes two or three inspirations of pure air, thereby prolonging the time it takes to bring about anæsthesia.

In the second place: During an operation about the head, face, or neck, there is nothing more annoying both to operator and narcotizer, than the interference with the hands and instruments of the surgeon necessitated by the frequent removal and replacement of the inhaler.

Finally: It not infrequently happens during the operation that it is required to crowd the ether, and this is difficult to do when the inhaler must be removed from the face for each addition.

To correct these difficulties the idea suggested itself to me to provide means for feeding the sponge without removing the inhaler from the face. This I have accomplished by passing a tube leading to the sponge through the top of the bag, at the upper end of which a small funnel is attached into which the ether is poured. It might be suggested that the Ormsby supply-tube, which is placed laterally on the face-piece, be added to the Parkinson inhaler, but the difficulty with this is, that in most positions of the patient's head, the ether, in order to reach the sponge has to work its way against gravity, and is very apt to flow into the patient's mouth.

This inhaler is essentially the same as that described by Dr. Parkinson, the difference lying only in the addition of the above-mentioned supply-tube, and in the omission of the air-cap.

To the upper part of the wire basket is attached a short tube (F), from the lower end of which branch out three smaller tubes (D, D, D,) which are open below, perforated on the inner side, and curved so that they can

grasp the sponge. A metal cap (B) with an opening in its top, placed laterally, is screwed on to tube F and with it holds fast the bag, which is perforated above. Around the cap (B) as an axis revolves a funnel (A), whose lower opening corresponds in size and position with the perforation in cap B (Fig. III.). In this position of the funnel, ether, when poured in, will flow through the tubes F and D, D, D, directly on to the sponge. When, however, a half revolution of the funnel is made, communication with the sponge is shut off. A small nail (C) protruding from cap B through a slit on the side of the funnel, prevents the latter from making more than one-half a revolution. The air-cap has been discarded simply because it has been found unnecessary. Some air will pass through the funnel if left open, and more, if desired, can be given by slightly tilting the mask from the face. Should the experience of others differ from mine in this respect, the air-cap might well be retained.

To sum up, the following seem to me the principal advantages of this inhaler after having used it in over two hundred cases:

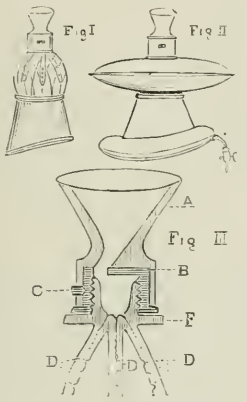

Fig. I. Skeleton of inhaler. Fig. II. Inhaler complete. Fig. III. Cross-section of funnel and supply-tubes.

1. Ease, rapidity, and a minimum of discomfort to the patient in bringing about anæsthesia.
2. Absence of interference with the surgeon in operations about the head, face, or neck.
3. Ability to crowd the ether very rapidly when occasion demands.
4. Smaller amount of ether required (twenty to thirty grammes frequently suffice to bring the patient under).
5. Considerable convenience to the narcotizer.

It will not be amiss for me to add here what seems to me the best way of using the inhaler. A clean sponge, large enough to fill the wire basket, should be placed between the three supply-tubes, and from five to ten grammes of ether poured upon it. The mask is brought close to the patient's face and held there till a certain degree of toleration of the ether is established. It is then placed tightly over the nose and mouth, and at required intervals from two to five grammes are poured into the funnel. It is most advisable to use a graduated chloroform dropper, for with it there need be no spilling, and the amount of ether poured out is better controlled. The mask should be held between the thumb and index finger of one hand, the little finger resting behind the angle of the jaw, drawing it forward, and the middle and ring fingers on the lower border of the inferior maxilla. This grasp enables one easily to tilt the mask, if a supply of air is needed, and leaves the other hand free to pour out the ether or to assist in holding the jaw forward.

This inhaler is now in regular use at the German Hospital, and is giving eminent satisfaction. The instrument is manufactured by Eisner, New York.

Foreign Body in the Ear for Twenty-one Years.—An interesting case of foreign body in the ear, which had remained without causing any urgent symptoms for twenty-one years, recently came under the notice of Dr. Pritchard. He was called to see a married woman on April 5th, and found her to be suffering from acute follicular tonsillitis (*The Lancet*). She complained of much pain in swallowing and of acute pain in the right ear, the temperature being 103° F. The throat inflammation quickly yielded to treatment, and in a few days the throat had resumed its normal condition, but the earache persisted. Interrogated as to whether she had had any ear trouble previously, she stated that for some years past she had suffered from occasional neuralgic pain and a sensation of "something being in the ear." She did not think she was particularly deaf, but had noticed lately that she had acquired the habit of turning her left ear when listening to any feeble sounds. She then stated that when a child, twenty-one years ago, she remembered placing a pea in her ear in imitation of her nurse, who was performing the sleight-of-hand trick of inserting a pea in the ear and withdrawing it from the nose. She placed a pea in her ear, but was unable to complete the feat. A medical man was sent for, but after repeated attempts all endeavors to remove the foreign body were abandoned, owing to her struggling. It was hoped the pea would "work its way out," and her friends always believed it had done so. Her sense of hearing, tested by a watch, was much impaired, and examination of the meatus revealed a large accumulation of wax. Warm oil was applied on two or three occasions, and the ear was syringed with warm water. After removal of some of the wax a dark roundish body was distinctly visible, adhering to the posterior wall of the canal. Syringing failed to remove it, and a fine silver-wire snare was carefully pushed beyond it and the body was dislodged, which on examination proved to be an ordinary pea. The pea was much shrivelled and a portion of it was covered with epidermis, its presence having set up a hyperplasia of the epidermal layer and a heaping-up of cells around that portion of the pea in contact with the canal wall.

Phenates of Bismuth.—Jasenski (*Arch. des Sciences Biologiques de St. Petersbourg*, T. ii., No. 2, 1893) finds that phenol-bismuth, cresol bismuth, and β naphthol-bismuth, when introduced into the stomach become decomposed there into their components under the influence of the gastric juice. A portion, however, escapes decomposition here, and passes on into the intestine, where it is finally split up. The phenol and cresol, separated from the bismuth, are entirely absorbed, eliminated in the urine as sulpho-conjugate acids, or combined with glycuronic acid; the β naphthol is only partly eliminated in this manner, the remainder passing unchanged through the whole length of the digestive tract, and being expelled with the fæces. In the urine of man the bismuth is not discoverable, being entirely eliminated in the

fæces. Notwithstanding the toxic properties of the phenols, none of these preparations have any toxic action even if given in daily doses of 5 gm. This is probably due to the extreme slowness of the decomposition which goes on in the intestine. The author therefore recommends these preparations in all cases where the ordinary preparations of bismuth and phenols were formerly employed.

The Modern Treatment of Sea-sickness.—A correspondent of the *British Medical Journal*, who has recently crossed the Atlantic says: "A formula which has been much recommended by Dr. Charteris, of Glasgow, and which has well stood the test of Atlantic Ocean experience, is based on the combination of 20 gm. each of chloralamid and bromide of potassium; both of them individually useful, but which seem to act better in combination, and may be flavored with licorice or tincture of orange-peel. A 'specialty' has been made of this under a 'registered' trade title, I know not by whose authority or for whose benefit. A very effectual and pleasant form in which to administer this compound is as follows: Tinct. aurantii recentis, ℥ iv.; chloralamide, ʒ ij.; pot. bromidi, ʒ ij.; aquæ chloroform., ʒ ij.; aquæ dest., ad ℥ viij.; dose. ¼ part. Chloralamide is incompatible with alkalies, and is soluble in about 1 in 20 of water. This combination is particularly valuable in the frequent cases of sea-sickness, with insomnia; it does not interfere with the digestion or temperature. Dr. Johnson, of the Cunard steamship Aurania, tells me that he has tried it extensively, and with excellent results. Where there is much pain as well as irritability, the sipping of ice-water is often very soothing; and it is here that cocaine tablets of $\frac{1}{20}$ or $\frac{1}{10}$ of a grain find their appropriate sphere of usefulness. They are usually prepared with chocolate, quickly eaten, and swallowed at intervals of half an hour or an hour. Where there is pallor, faintness, and more or less tendency to 'collapse,' as in some severe cases, very great relief may be found from the use of nitroglycerine tablets. The tablets have the nitroglycerine in solution in chocolate in a perfectly safe, stable, portable, and palatable form. Tablets of $\frac{1}{200}$ of a grain are a sufficient dose to ward off sea-sickness. The small bulk, precise dose, and quick action, if well munched and swallowed, render this mode preferable for administering nitroglycerine."

Night Air.—Before we can hope to fight consumption with any chance of success we have to get rid of the night-air superstition. Like the dread of cold water, raw fruit, etc., it is founded on mistrust of our instincts. It is probably the most prolific single cause of impaired health, even among the civilized nations of our enlightened age, though its absurdity rivals the grossest delusions of the witchcraft era. The subjection of holy reason to hearsays could hardly go further. "Beware of the night wind; be sure and close your windows after dark!" In other words, "Beware of God's free air; be sure and infect your lungs with the stagnant, azotized, and offensive atmosphere of your bedroom." In other words, "Beware of the rock-spring; stick to sewage." Is night air injurious? Since the day of creation that air has been breathed with impunity by millions of different animals —tender, delicate creatures, some of them—fawns, lambs, and young birds. The moist night air of the tropical forests is breathed with impunity by our next relatives, the anthropoid apes—the same apes that soon perish with consumption in the close, though generally well-warmed, atmosphere of our northern menageries. Thousands of soldiers, hunters, and lumbermen sleep every night in tents and open sheds without the least injurious consequences. Men in the last stage of consumption have recovered by adopting a semi-savage mode of life, and camping outdoors in all but the stormiest nights. Is it the draught you fear or the contrast of temperature? Blacksmiths and railroad conductors seem to thrive under such influences.—*Good Health.*

The Universal Increase of Insanity.—Why is it that the ratio of insanity in all civilized countries, notwithstanding the increased asylum accommodations and the vastly improved treatment, is steadily increasing, having gone up in England since 1862 from 1.81 to 3.11 per cent., and even more than that in this country. Will statesmen and philanthropists turn for a time from the well-beaten road of ordinary political measures and charities, to point out a remedy and dam at the source this ever broadening and deepening stream, whose tributaries are in almost every town and hamlet in the land. The causes are so many and so varied, from heredity down the long line of worries, of alcoholic and narcotic poisoning, that the wisest statesmanship and the most profound study of psychology and mental science must be brought into action to meet intelligibly abuses and habits so closely entertwined with almost every phase of social and industrial life. As there can be no one specific, the remedy must be general, gradual, and constant. It has been well said that the manifestations of insanity are nothing further than distorted or diseased manifestations of mental activities, which by themselves are present in every man. These mental activities, the outgrowth of physiological conditions, to a certain extent hereditary, are increased or distorted by different influences. An influence which to one would be comparatively harmless, to another would be productive of disastrous results. The education of the will and the training of the intellect and sentiment are the main factors in building up a harmonious and healthy physical and mental organization, and through these channels must come these healing influences which will calm the turbulent passions which bring those influences which excite unhealthy mental activities under the control of reason.—*New York Medical Times.*

The Digestibility of Tripe.—Tripe consists of the soft muscular walls and mucous membrane of the stomach of ruminant animals with a small proportion of delicate omental fat adhering, from which, however, all fibrous portions of the serous covering, or peritoneum, have been removed. From frequent experiments it has been proved that tripe stands high in the list of albuminous substances that are quickly acted on by the gastric juice and reduced to a state of solution, and has therefore acquired a reputation for digestibility. But plain boiled tripe in itself is a very insipid article of food, and in order to make it palatable the art of the cook has to be invoked, which, while making it more "savory," causes it often when so served to be an offence to the stomach. The usual mode of serving tripe in England is to boil it with milk and onions, and there can be little doubt that such a combination is not particularly digestible. Tripe is also sometimes fried in butter, but unless very carefully cooked it is apt to become leathery. If only plainly boiled in water it requires a considerable amount of condiments in the shape of salt, pepper, and mustard to make it acceptable to the palate. Therefore tripe, as usually cooked, though an excellent dish for strong stomachs, is, owing to the ingredients added to it, not always so suitable for persons of weak digestion as has been supposed. One interesting point regarding the consumption of tripe is the local favor it receives in different parts of the country. It is a favorite dish among the artisans of the large towns in the midlands, while it is apparently disregarded in the south and west. A similar local partiality prevails in France, where Normandy has acquired a special repute for the dish *tripes à la Normandie*, which is served in many Parisian restaurants as a delicacy of no mean merit. London also consumes a large quantity, where during the winter it is a favorite supper dish among the artisans and lower middle classes. The preparation of tripe, as far as London is concerned, is in the hands of only a few firms, who supply the small retail shops. London tripe, moreover, has obtained a high repute on the Continent, one firm exporting annually $200,000 worth, chiefly to Russia and Baltic ports.—*The Annals of Hygiene.*

THE TREATMENT OF ITCHING.[1]

By EDWARD BENNET BRONSON, M.D.,

NEW YORK.

In the management of pruritus, as of any other disease, the first consideration should be directed to what causes the trouble. The adoption of measures tending to remove any accidental conditions or influences through which it may be occasioned, is therefore important. Such causes include, besides various local sources of irritation, certain remote or general diseases, and furnish the *indicatio causalis* in its more limited sense. This, however, states the scope of the problem only partially. What is of most importance first, is to establish principles of treatment fitted to those more special and most essential causes that constitute the necessary conditions of the disease, and whence we derive the *indicatio morbi*. These causes I have endeavored to trace elsewhere,[2] and it is they which afford the only intelligent basis for the therapeutics of pruritus.

We have seen, first of all, that the chief underlying condition in pruritus is hyperæsthesia, whether in its common signification of an excessive irritability of the sensory nerves, or in the sense of an excess or engorgement of sensation. The prime indications, then, are to allay irritability and to divert or annul the excess of nerve excitement. The natural impulse of every afflicted animal is to resort at once to what is the simplest mode of relief, namely, to divert the irritation or sensory engorgement by scratching. But while affording temporary relief or relief that in ordinary, or what may be termed physiological, itching may be permanent, in morbid pruritus, in pruritus dependent on a pre-existing state of hyperæsthesia, the effect of this method is to augment the excitation in the aggregate—which augmentation will almost surely be followed by another engorgement with a greater access of the pruritic excitement. Furthermore, the resulting hyperæmia, itself a common exciting cause of itching, will very likely do more than offset the temporary diversion that the scratching affords, and besides this, the injury done the epidermis renders it each time more vulnerable and more sensitive to irritating contacts. Scratching is an abuse of what would *à priori* seem to be a rational method of treatment.

Should the morbid irritability which is the predisposing condition in pruritus essentialis be dependent upon some removable cause, the problem becomes a comparatively simple one. Thus, if due to rheumatism or gout, especially when a recent effect, by the use of anti-rheumatic or antilithic remedies the hyperæsthesia may disappear and with it the pruritus. Similarly, in appropriate cases, cholagogues, purgatives, or diuretics might possibly suffice to effect a cure. But as a rule, the hyperæsthetic tendency must be accepted as a necessary and more or less permanent condition, and the best we can do is to avoid or mitigate the consequences. As in all irritable conditions, the most important thing is to secure rest, first by removing so far as possible all local excitants, and, that not sufficing, by the employment of calmants.

[1] Read before the American Dermatological Association at its 17th annual meeting, held at Milwaukee September 5, 1893.

[2] See Etiology of Itching in the MEDICAL RECORD of October 24, 1891, and also the same subject under Pruritus Essentialis in Morrow's forthcoming System of Dermatology.

A. **Measures to Remove Local Excitants.**—These will include, first of all, such as directly tend to prevent scratching. To admonish the patient to refrain from this is usually of little avail. Restraint may be possible during waking hours, but at night, when the trouble is always at its worst, and especially during the state of somnolence midway between sleeping and waking, no will-power can prevent it. It can only be avoided by first mitigating the *besoin* through the aid of antipruritics. It is of some advantage, however, for the patient to know that relief may often be obtained through other tactile diversions than those which are effected by the sharp finger nails, as, for example, simply by firm pressure of the part, or by stroking the itching surface with the finger pulps or with a soft cloth or brush (especially if first lubricated with vaseline), using some pressure but without rapid motion. Irritating contacts of all sorts should be most scrupulously avoided. Attention should be given to the underclothing. Woollen is almost never tolerated. The clothing next the skin should be of the softest material—cotton, linen, or possibly silk. Of further importance is the avoidance of immoderate temperatures, whether of heat or of cold, and especially of sudden changes, which are peculiarly apt to excite itching. The temperature of the surface should be kept as equable as possible.

The local excitants may not only be extra cutaneous, but also intra-cutaneous. Often they are incidental to the trophic changes of one of the so-called pruriginous diseases; in which case the treatment of the pruritus is included in that of the disease of which the itching is a symptom. When they arise from toxic materials conveyed to the skin by the blood, we endeavor to eliminate these materials by depurative remedies, more especially diaphoretics and diuretics; while disturbances of the nerve-terminals that are directly transmitted from the interior, are best relieved by means of the substitutive irritants to be considered in a later section (*D.*).

These measures failing or proving insufficient to secure the desired rest, it becomes necessary, in pursuance of this object, to have recourse to certain sedatives. Some of these, that are used internally, are designed more particularly to neutralize the hyperæsthesia; others, including both internal and external remedies, serve rather to directly annul the pruritic excitement.

B. **Sedatives.**—Used internally these are apt to be disappointing. The degree of general sedation that is required to affect the nerves of the skin in so intense a disturbance as pruritus often is, affords a sufficient reason why this method of treatment is usually objectionable. Further than this, the depressing and atonic after-effect on the nervous system tends to exaggerate the general hyperæsthesia, which is already essentially an atonic condition, and thereby increase the tendency to itching. Especially objectionable on this score are most of the narcotic sedatives. The bromides, on the other hand, are often indispensable, and may be required in liberal doses. It is important to avoid the enervating effects of loss of sleep, and for this purpose sulphonal or some other hypnotic is occasionally needed. In connection with this class two internal remedies, which have been especially recommended by Bulkley, are here worthy of mention. They are cannabis indica and gelsemium. The former is known to be a cutaneous anæsthetic as well as analgesic, and by virtue of the former quality should be useful in pruritus. Whether its usefulness in this disease is chiefly owing to this or to another quality, which will

be referred to later in connection with the sensory stimulants of the next following class, is uncertain. Gelsemium has proved of benefit in some cases (more especially, according to the writer's experience, in protracted cases of urticaria), but the doses required are so large as to forbid their long continuance. It will be referred to again under motor depressants (*F.*). Finally, the antipyretics phenacetine and antipyrine have some effect upon pruritus, though less than upon the sensation of pain.

The local sedatives used in this disease are generally far more satisfactory in their effects than the remedies just considered, especially where the disease is limited in extent. They are for the most part agents that tend to retard vital action. The fact that many of them are antiseptics, probably implies something more than mere accidental coincidence. Under both aspects their effect is to depress, if not impair, vitality. Incidentally they are nerve depressants. Acting upon the superficial nerve-endings, they tend to retard the so-called "nerve vibrations," or molecular movements. How they exert this action through the intact epidermis is somewhat difficult to understand, but of the effect produced there can be no question. Typical among the remedies of this class is the group which includes carbolic acid, salicylic acid, salol, and thymol, all antiseptics, and all having undoubted virtues as antipruritics.

Carbolic acid, the most important member of this group, is perhaps, all considered, the most reliable and most generally useful antipruritic which we possess. It was well named by Unna, "the opium of the skin." In pure solutions, or in combination with other remedies, and even when comparatively weak, its quieting effect on pruritus rarely fails. The two to five per cent. solutions which are most commonly employed, though often of benefit, do not, however, bring out the full antipruritic effect of which this drug is capable. Watery solutions require to be used of less strength than those in oils or fats. They are more apt than the latter to be corrosive, and also, being more quickly absorbed, are more liable to be followed by general toxic effects. For these reasons carbolic acid is preferably employed in oils or ointments, for, though the absorption is slow, the effect passes off less quickly, and the stronger solutions are comparatively safe. With proper precautions as to its use an oily solution of from twelve and a half to twenty-five per cent. may be used with perfect impunity, provided the area to which it is applied is of moderate extent.

The following "antipruritic oil" has been largely employed by me for years, both in the local and in the so-called universal forms of the disease, with no more untoward results than now and then a trifling dermatitis, when through oversight the patient has been allowed to make the applications too frequently, or has continued them too long. The formula is:

℞. Acid. carbolic..... ℥ j–ij.
Liq. potass..... ℥ j.
Ol. lini..... ℥ j.
M. Sig.: Shake before using.

An alkali and an effective keratoplastic agent (the linseed oil) serve both as adjuvant and corrigent to the action of the carbolic acid. To correct the disagreeable odor of the linseed oil, a drop or two of the oil of bergamot may be added.

Salicylic acid and salol, though less energetic in their effects, act similarly to the carbolic acid. They may be used in combination with other drugs, or by themselves in oil or ointments, or sometimes alcohol, and also in superfatted soaps.

Thymol, which is a cutaneous anæsthetic as well as antiseptic, is also in certain cases of universal pruritus an admirable antipruritic, but on account of its irritating effect, cannot be used where the skin is very sensitive. It is well combined with menthol in a three per cent. (of each) alcoholic solution. Doubtless other remedies of like character might, with advantage, be added to this group.

The corrosive chloride of mercury is another well-known antiseptic which has also a reputation as an antipruritic. It is difficult to explain the latter action, except by regarding this agent as a local sedative by virtue of its hostility to all forms of life, and its ability to retard excessive vital action. The marked anæsthesia of the skin that is produced by concentrated solutions is doubtless due to this property.

Certain other local sedatives of the skin, though not in the antiseptic group, yet apparently owe their effect to a similar retardation or arrest of molecular movement in the affected sensory nerves. Such is cocaine. The decided anæsthetic action of this drug upon mucous membranes, upon abraded cutaneous surfaces, or when used subcutaneously, would seem to indicate it as a specific in pruritus. For two reasons it has proved disappointing: First, because of the difficulty of making its action felt through the intact epidermis, and second, for the reason that any tissue, when long or frequently subjected to its action, suffers a certain atony and enervation that seem to render it more predisposed after than before to the irritation or irritability the drug was intended to alleviate. This latter is a common effect of prolonged use in the eye or nose, and I think I have verified the occurrence of similar consequences after prolonged use in pruritus progenitalis. These objections by no means preclude its use entirely. It is often resorted to with most satisfactory results in localized forms about the mucous orifices, upon raw or abraded surfaces, and sometimes with appreciable effect even where the epidermis is apparently intact.

Other sedatives of this class are cyanide of potassium (℥ j., water, Oj.), chloroform (℥ j., glycerine, ℥ ss., water, ℥ viij.), and camphor in combination either with an inert powder or with chloral, the mixture being properly diluted. It is probable, however, that the last-named remedies act not only, often not chiefly, as sedatives, but partly as substitutive irritants—a class to be considered later on. Of a somewhat similarly complex nature is the antipruritic effect of hot water, which calms the nervous excitement, apparently not only by direct sedation of the sensory nerves, but also by its general relaxing effect, removing pressure or constriction of the nerves; and furthermore, at the beginning at least, it is a powerful substitutive irritant. To be effective, the temperature should be over 100° F., or as hot as can be tolerated, and the applications should be prolonged for several minutes.

It is evident that the impaired conductibility of the sensory nerves with hypopselaphesia, which, as I have endeavored to show, is in greater or less degree an essential condition of the pruritic sensation, though it is not necessarily antipathic to the hyperæsthesia, nevertheless affords special and independent indications for treatment. While the condition of hyperæsthesia calls for depression, or at least repression, that of hypopselaphesia demands a certain kind of stimulation. Hence we distinguish in the therapeutics of pruritus a third class of remedies.

C. **Sensory Stimulants.**—The kind of stimulation which it is intended by these to effect is not of that general character which simply augments the common irritability of the skin, but it tends rather to enhance its higher and perceptive sensibilities. By its action the function of the sensory nerves is so improved that sensations of contact or temperature, which through obstruction are exaggerated into the fret of itching, find freer channels of escape and a more normal interpretation in the sensorium. It is more especially in such forms of pruritus as are associated with hypopselaphesia as a predisposing cause, as, for example, in pruritus senilis, that remedies of this class are indicated. An example of this kind of stimulation has already been alluded to in speaking of the mechanical modes of relief that may be substituted for scratching. It probably constitutes an inci-

dental effect in the action of various antipruritic remedies more properly belonging to other classes. There is one, however, that would seem to legitimately belong here, namely, electricity, whether in the form of galvanism or faradism. Under one form or the other this agent has sometimes proved to be of decided benefit. Perhaps the most effective agents of this class are those that act upon the nervous centres. Thus strychnia, in those cases of pruritus which we may call atonic, is a remedy of value. Cannabis indica, which is a decided stimulant to the nervous centres and the higher sensibilities, may owe its efficacy in this disease quite as much to this fact as to any anæsthetic effect upon the commoner sensation of the skin. Its action in pruritus, therefore, would be analogous to that which has given it its reputation as a remedy for sexual impotence.

We have seen that a frequent cause of cutaneous pruritus is reflex irritation. Herein is discovered another factor in the indicatio morbi. Reflect the irritation back to its original source, or taking the initiative as aggressor, invade some inoffensive region that may be made to sympathize with the skin, and make it bear a part of the skin's burden. It suggests our fourth class of remedies.

D. **Substitutive Irritants.**—The rationale of the good effect often witnessed in cutaneous irritations from cathartics, hepatic stimulants, and diuretics is that by these means a remote disturbance is created into which is diverted a portion of the cutaneous excitement. It is a method of treatment that can seldom be spared, and the aid thence derived may make all the difference between success and failure of local and more direct measures. But in pruritus the sympathetic substitution is not always effected between the skin and a remote or interior part, but between different portions of the tegumentary surface, and what is more, between different kinds of sensation in the skin. Pain is antipathic to pruritus, and one may be substituted for the other. The effect of smarting or stinging applications in relieving pruritus is thus explained. It doubtless explains part of the effect of thymol, chloroform, hot water, and other burning or pungent applications. It is analogous to the action of the "sensory stimulants" described above, where tactile impressions, which on account of the impaired or occluded media tend to degenerate toward common sensation, are deflected into the channels of higher special sense. A similar interchange occurs, as we have already seen, between the contact sense and the sense of temperature. Both cold and heat beyond a certain point annul the sensation of itching. Slight changes in temperature often evoke it, but so long as the sense of temperature remains at all noticeably affected, it dominates the itching, which, for the time being at least, remains in abeyance. We sometimes avail ourselves of this substitutive action by using cold applications, but the stimulation which these cause is apt to aggravate the pruritic excitement afterward. But a remedy which is one of the best palliatives of itching that we have, and which is especially noteworthy in this place, is menthol, together with the peppermint preparations generally.

Menthol is commonly referred to as an anæsthetic, but it relieves itching as it relieves pain, not by direct inhibitory action on the molecular movements of the sensory nerves as do the true anæsthetics, but chiefly, as I believe, if not solely, through substituting an exaggerated temperature sense for the perturbed sense of contact, or for the sensation of pain. Goldscheider,[1] who has carefully investigated this subject, attributes the sense of coolness that follows the application to the skin of menthol or other peppermint preparation, to a specific action on the special nerves of temperature, causing what is virtually an hyperæsthesia of the temperature sense. He also found incidentally that when a portion of the skin, as for example the forehead, had been rendered insensible to cold by application of ice and then afterward mentholized, the sensations of burning, pins and needles, and the like which the cold produced, remained unaffected in spite of the menthol; from which it is inferred that the latter is not a true anæsthetic. Of its antipruritic virtues, there can be no question. It is usually employed in alcoholic solutions (grs. v.–x. to ℥ j.) and may be used in ointment. It is also with advantage combined with salol or thymol.

A fifth class of remedies often indicated in pruritus essentialis may be designated as follows:

E. **Alteratives of Cutaneous Nutrition.**—They include not only absorbent and anticatarrhal remedies to remove the products and curtail the processes of incidental inflammations which may act as contributory causes of the itching, but such agents as tend to control blood-supply and overcome hyperæmia. In this way act diaphoretics, and possibly diuretics, as well as by their substitutive and eliminative or depurative action. Thus it is probable that jaborandi, which is extolled by so many writers for its efficacy in this disease, acts in all three ways. It determines excitement to the secretory instead of the sensory organs of the skin; it promotes the elimination of noxious matters which are irritants to the nerves, and, finally, the diaphoresis depletes the blood-vessels. This drug is especially useful when the skin is hot and dry, and where it has become the depot of noxious materials deposited from the blood, as, for example, in the itching of icterus.

The local remedies belonging to this class include certain resinous or tarry substances which are especially indicated in associated catarrhal conditions, and have a certain controlling effect upon hyperæmia. Such are ichthyol (five to ten per cent.), tumenol (twenty-five per cent. or pure), occasionally tar, resorcin (three per cent.), and benzoic acid or benzoin.

When considering the etiology of pruritus, one of the incidental causes of the deranged function of the sensory nerves was ascribed to a condition of impaired nutrition in the skin with defective metabolism. In conditions such as this it is a commonly accepted opinion that agents which promote oxidation are especially indicated. Now it is a significant fact that a large proportion of the remedies that allay itching are oxidizing agents; while, on the other hand, a reducing agent rarely if ever has any direct antipruritic effect. It is the keratolytic substances, which are also as a rule oxidizing agents, from which we largely select our antipruritic remedies. Such are the whole group of antiseptics, the mineral and vegetable acids, and also the alkalies. The oxidizing effect may in many instances be subordinate to other actions they possess, but a property common to them all can hardly fail to have some therapeutic significance.

Led by these considerations, it seemed to me that the solution of hydrogen peroxide should be an appropriate remedy for pruritus, and since I first began its use, some few years ago, I have had abundant verification of the fact that it has antipruritic virtues, more especially in cases of pruritus universalis. It may be used as a toilet wash two or three times a day. In place of this, and perhaps with equal benefit, I have also used an aqueous solution of ozone known commercially by the hybrid name "aquozone."

The final indication for treatment which the etiology suggests, relates to the hyperkinesis of the arrectores pilorum muscles. Inasmuch as the spasm affecting these muscles is always secondary to some other condition, measures which relieve the latter will generally be the ones best calculated to dispose of the former, and ordinarily no more special treatment of this contributory factor is needed. But to be complete our classification of remedies should embrace one more class.

F. **Motor Depressants.**—Among the internal remedies already mentioned gelsemium and jaborandi belong certainly to this class, and it is very possible that to this fact they owe in some measure their antipruritic effects. Another remedy which, though recommended more especially in urticaria, should be mentioned here is atropia. It is probable that the good effect of this drug in urticaria

[1] Archiv f. Phys. u. Anat., 1886, p. 555.

when used in full doses, such as are always required to produce this effect (from one hundred and fiftieth of a grain upward), is due not to the primary, but to its secondary, action. The primary action, attendant upon the smaller doses tends to excite muscular contractions and cause increased vascular tension. In its secondary action its effect is just the contrary of this; the muscles relax, the vessels are dilated. It is doubtless through release of tension in the cutaneous muscles that this drug acts so favorably in the urticarial hyperkinesis.

Of the local remedies belonging to this class the first place unquestionably belongs to the hot-water applications. Here also might perhaps be included certain local sedative remedies, such as hydrocyanic acid, the cyanide of potassium, conium juice, tincture of arnica, and chloroform, all of which are decided depressants of motor action.

Having thus in a general way met the various indications for treatment in pruritus essentialis, it remains to briefly apply the therapeutic principles laid down to certain special forms of the disease. It must be confessed that, however clear these principles may appear in the abstract, to apply them in the concrete, *i.e.*, to individual cases, is not always easy. Often, and in large degree, we must rely on empiricism in its better sense. To know the *rationale* of things is most desirable, but in practice experience is often truer than theory.

Thus in pruritus senilis, while theory suggests more especially the sensory stimulants described under *C*, so complex often are the morbid conditions involved in this form of the disease that recourse must be had to remedies of very diverse nature. In some respects theory and experience here correspond. The successful employment of faradism in senile pruritus, that has received abundant testimony, is scarcely susceptible of any better explanation than that afforded by the theory of its restoring or stimulating an impaired sensory function. It by no means always succeeds, but in uncomplicated cases it rarely fails of good effect if persisted in. It has seemed to me, however, that it was often effective when applied only to the spine, and not directly to the pruritic surfaces. It is best administered by means of a brush electrode. The cold douche is another remedy in the same line that is sometimes of benefit and is best used in the morning. In one or two cases patients have assured me that prolonged relief was obtained by certain frictions of the skin at night, as with the rough mitten sometimes used in bathing. Such a remedy, however, could rarely be recommended as a safe one. For internal use the strychnia and cannabis indica, which are stimulants to the nerve centres, are appropriate remedies, and have already been referred to. The tincture of cannabis indica may be given in doses gradually increased from ten drops to a scruple or half a drachm, three times a day, unless it should disturb the digestion. The indicatio causalis in this disease opens a wide field for therapeutic measures Those included in the class of "alterations of cutaneous nutrition" [*E*] are particularly important. Internally antilithic remedies, alkalies, diuretics, and cholagogue cathartics, are required to meet special indications. Locally we may employ the alkaline baths, the hydrogen peroxide, and the oxidizing substances of the antiseptic group. Nor can the sedative applications of class *B* be dispensed with. Which one will answer best can often only be determined by trial. A ten per cent. solution of salol in benzoinol is of some use; the carbolic oil mentioned above is more powerfully antipruritic, but requires caution It is best suited to limited areas of itching. Menthol also acts admirably in many cases, either alone, or what is better, in combination with some emollient substance. If too strongly or too frequently applied it is liable, like carbolic acid, to irritate and thus render the skin more sensitive. A remedy highly extolled by the English is liquor carbonis detergens (a three per cent. solution in water).

In pruritus hiemalis an all important measure of treatment is protection against cold The sole cause of winter pruritus, aside from a special predisposing hyperæsthesia, is lowered temperature. The first cold day evokes it, and, after raging through a succession of cool days, the first warm day will make it disappear till again the weather changes. The temperature effect may be forestalled to a certain extent by protecting clothing. A minor point, though by no means an unimportant one, is, that in making changes of clothing the undergarment should remain as light as that worn during the warmer weather. If wool is required it should be worn outside this thin undergarment. Sometimes it is well to bandage the legs (where the trouble is always worst), at least for the latter part of the day. At night a wet pack for this portion of the body often gives much relief. A five per cent. salol superfatted (Eichhoff's) soap may be moistened and smeared over the itching surfaces, where it is allowed to dry on. The surest relief when the itching areas are of limited extent (and such often is the case) is afforded by the antipruritic oil mentioned above. Each morning care should be taken to dress any excoriated or inflamed spots, due to scratching, with some healing, emollient application such as the Lassar paste. Otherwise there is much danger of eczema being developed. Indeed, I believe it possible that a large proportion of the chronic eczemas of the legs owe their first inception to this very cause, *i.e.*, the scratching occasioned by pruritus hiemalis.

In pruritus of the genito-anal region, while all possible is being done to remove or abate any accidental cause which may be discovered, the choice of direct antipruritic remedies will depend much on the nature and complications of the case. Special treatment is required for cases associated with eczema or other inflammatory disease. For the itching, perhaps no remedy is more generally useful than hot water. The patient squats over a vessel in which there is water as hot as the hand can bear, and after a little the temperature can be tolerated still higher. With a handkerchief held as a swab between the fingers, the water is sopped on for a period of three or four minutes. The part is then gently dried with a soft cloth and well powdered with talc or other inert substance. In all of the forms of pruritus in this region carbolic acid is of very great value, but as already intimated, to be of much avail it must be used strong. The above-mentioned oil is especially useful in these regional forms, but should not be used too frequently nor where much inflammation prevails. Menthol in a thin ointment (grs. v.–x. to ʒ j.), or the peppermint water, is also extremely useful, and salol may be added with advantage. All of them should be followed by copious applications of a soothing powder. In some cases, more especially where the parts are sore or abraded from long scratching or rubbing, the greatest relief will be afforded by cocaine, whether in a four per cent. watery solution, or, what is better, in some soothing emulsion or thin ointment.

For pruritus vulvæ some of the special remedies advised are, painting the parts every night with compound tincture of benzoin, or, in some cases where the surface is thickened from long irritation, occasionally touching the affected region with a rather strong solution of nitrate of silver (℈j.–ʒ ss. in water ʒ j.). Many authorities have advised applications of corrosive sublimate (one-fourth to one grain, water one ounce), or the following prescription, recommended by Bartholow, will sometimes be found useful:

℞.	Hydrarg. chlor. corros.	1 part.
	Alum.	20 parts.
	Starch	100 parts.
	Water	2,500 parts.

Whenever the itching affects the mucous membrane it can generally be relieved by cocaine.

For pruritus scroti Crocker advises painting the part with a solution of silver nitrate (grs. x. to ʒ j.) in sweet spirits of nitre. In inveterate cases I have sometimes employed, with considerable success, a method of treatment first suggested by Vidal. It consists in scarifying the entire itching and usually thickened surface with

Squire's scarifier or an ordinary scalpel. The incisions need not go much beyond the epidermis. But there is an advantage in drawing a little blood. Afterward the part is dressed with a thin layer of Lassar paste which may contain a little cocaine. The layer should be thin, for it is a fact of common experience that ointments are rarely well borne in pruritic affections of the genito-anal region.

The remedies most useful in pruritus ani are the same, generally, as those for the vulvar and scrotal forms. Sometimes relief can be obtained here only through substitutive irritants. A liniment containing chloroform or camphor in sufficient strength to cause considerable smarting will occasionally give relief to the intense itching which can be secured in no other way. A method suggested by Allingham would perhaps belong more properly to the class of sensory stimulants: A bone plug an inch and a half long, and about as big in diameter as the end of the forefinger, is slipped into the anus on retiring, and retained in position through the night by means of a compress.

CASES OF ALARMING EPISTAXIS OF GRIPPAL ORIGIN, AND DANGERS OF POST-NASAL PLUGGING.[1]

By A. W. de ROALDES, A.M., M.D.,

PROFESSOR OF OTOLOGY AND LARYNGOLOGY IN THE NEW ORLEANS POLYCLINIC; SURGEON IN-CHIEF OF THE EYE, EAR, NOSE, AND THROAT HOSPITAL; PRESIDENT OF THE ORLEANS PARISH MEDICAL SOCIETY; FELLOW OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION; MEMBER OF THE FRENCH LARYNGOLOGICAL SOCIETY, ETC.

With but limited time wherein to justify the honor conferred upon me to appear before this meeting, I have hurriedly collected my notes on a few cases of serious epistaxis of grippal origin. My only justification in selecting a subject so frequently discussed as epistaxis lies in the fact that its connection with the pandemic visitation of influenza needs more than the passing notice given it by modern observers. I hope, also, to elicit your views and experience on this subject, and to affirm your condemnation of the still too general practice of post-nasal plugging in cases of hemorrhage.

Case I.—My first case is the one of Mr. B——, a lawyer, aged thirty-eight years, married, who has always enjoyed a strong and healthy constitution until December, 1890, when he is stricken down with an attack of influenza which leaves after it severe and frequent headaches. A year after, on January 29, 1892, patient is again taken sick with a second attack of influenza of a more violent type, characterized, this time, by unusual febrile and nervous excitement. When scarcely convalescent, during the night of March 4th, Mr. B—— begins to bleed freely from his left nostril. His family physician, Dr. George K. Pratt, is called upon at once. On arrival he finds that the bleeding, after lasting fifteen minutes, has stopped spontaneously, to return, however, that morning in a more violent form, notwithstanding the use of a very hot solution of tannin. In the absence of Dr. Pratt, Dr. Charles Chassaignac is hurriedly sent for, as patient's weakness is quite marked. Other general methods having failed, the doctor concluded to use a piece of gauze somewhat in the umbrella fashion; in this glove-like hollow, absorbent cotton was packed.

Hemorrhage had discontinued when Dr. Pratt came in, but started again during consultation of attending physicians, when it was decided to plug posteriorly and then anteriorly. The right nostril began to bleed; had therefore to be plugged anteriorly. Blood then found its way through the nasal canal at the puncta lacrymalia, and at intervals in the throat, and also externally.

March 5th.—I then visited the patient in the morning at the request of the attending physicians. Found him weak, but hemorrhage having stopped at that time, advised a plan of expectation and his removal to the Eye, Ear, Nose, and Throat Hospital in case of recurrence.

Hemorrhage recurred in the afternoon, when he was brought to the hospital at 4 P.M., where he was received by my friend and assistant, Dr. Charles J. Landfried, to whom I am greatly indebted for his valuable collaboration in the management of the case and for some of the clinical notes thereon.

After removal of plugs Mr. B—— bled profusely. The nostrils were washed with a solution of boracic acid in very hot water, a twenty per cent. solution of cocaine made use of, and the seat of the hemorrhage located at the posterior part of the nares on the crest of a septal ridge, on a line with the inferior turbinated body.

The hemorrhage was practically controlled with the galvano-cautery, but the patient was so thoroughly exhausted that I thought it advisable to proceed at once with a continuous antero-posterior packing. A strip of iodoform gauze, doubled on itself, is carefully but quickly inserted between the opposing surfaces, and the ends are firmly matted down with a flat applicator in the lower meatus, taking care, however, not to push the gauze back any farther than the choana. The packing is continued until it has reached the upper limit of the ridge. To insure its fixity, it is built upon with additional strips until the middle turbinated body is reached, when the gauze is inserted in the crevices between that organ, on one part, and the septal and lateral walls of the nostril on the other. The dressing is completed by filling up the left nasal chamber with strips of gauze.

Upon examination the right nostril is found comparatively free, but the drums in both ears are found to be highly hyperæmic, and the patient complains of severe pains. That night both ears began to discharge a sero-sanguinolent liquid.

March 6th.—The hemorrhage having recurred it was quickly controlled by a new packing.

March 9th.—Packing removed and nostrils properly irrigated.

March 12th.—A renewal of the bleeding takes place, when it is thought necessary to proceed to a third continuous antero-posterior packing, this time in bed on account of the extreme weakness of the patient. This third dressing was left *in situ* five or six days, and allowed to eliminate itself spontaneously, the precaution being taken to cut the ends of the strips of gauze as they present themselves in the oro-pharynx, or at the entrance of the nostril. I will mention that during all this time patient evidenced signs of mastoid implication on the left side, this trouble being finally corrected by appropriate treatment of the ear.

March 16th.—Mr. B—— is seized with fever, which is the initial symptom of an attack of pseudo-rheumatism presenting the form of subacute polyarthritides, approaching in their onset and character infectious pseudo-rheumatism.

March 28th.—Patient is considered sufficiently well to be removed to his home, where his family physician had to contend against a return of the rheumatism during three days.

March 29th.—Was only then able to visit his office on crutches. Had by this time lost fifty pounds. Was subsequently treated for his hypertrophic rhinitis and nasal spur.

To-day, only, more than one year since his grippe and epistaxis, is Mr. B—— beginning to feel like himself. It is to be noted, though, that his violent and frequently recurring headaches, which had followed his first attack of influenza, have never returned from the date of his final hemorrhage.

Case II.—Dr. H——, aged sixty, of sound parentage, an inveterate smoker of cigarettes, is a sufferer of chronic rhino-pharyngo-laryngitis, but very active and in every other respect of a healthy constitution. No history of any previous hemorrhage. Was scarcely convalescent from a severe attack of influenza, which was at that time raging in his locality, when, on January 13th, he was

[1] Accepted as a candidate's thesis for Fellowship in the American Laryngological Association.

seized, while blowing his nose, with a severe epistaxis. The hemorrhage was so abundant and so persistent, notwithstanding all the attempts made to stop it, that the doctor concluded to take the train to New Orleans with the intention of coming to the Eye, Ear, Nose, and Throat Hospital.

The bleeding became so violent on the train, and the patient was so weak, that upon arriving at the depot his friends hastily repaired with him to the Charity Hospital, a short distance off.

My colleague, Dr. R. Matas, who was at the time in attendance in his wards, at once took charge of the case, and considering the abundance and the duration of the epistaxis, as also the extreme pallor and weakness of the patient, concluded to plug at once the posterior nares on the affected side; both nostrils had also to be plugged anteriorly. Then only did the hemorrhage stop. The patient was then transferred to the Hôtel Dieu. Five days after I was asked to join my *confrère* in consultation. The posterier plug, which was found firmly impacted, was removed by means of a curved post-nasal forceps. It was impregnated with a foul discharge of a very offensive odor. A severe purulent rhino-pharyngitis and a double otitis media suppurativa were not long in developing, and required the careful attention and constant direction of one of my assistants, Dr. Charles J. Landfried, before the double complication could be mitigated. Our patient's general condition was then thoroughly examined into without finding any organic trouble. The day after the removal of the plugs a swelling of a reddish, shiny appearance was noticed on the left side of the bridge of the nose, near the inner angle of the eye. It was the beginning of an attack of erysipelas, which was ushered in by a high fever and delirium. The disease travelled all around the face and scalp, and during twenty days we more than once despaired of the life of our *confrère*.

A month after his discharge I had occasion to make a careful rhinoscopic examination, which revealed the existence of a rhino-pharyngo laryngitis, with a well-defined septal ridge in the affected nostril, which impinged on the corresponding swollen inferior turbinated body in the rear part of the nasal cavity. The right side was rather roomy.

A treatment of this local condition was advised, but not followed, owing to the anxiety of the doctor to return to his practice. When last heard from he informed me that in September last he had a recurrence of the hemorrhage lasting ten hours, which he finally controlled by an antero-posterior plugging with absorbent cotton. He adds that it has taken him more than a year to recover his former strength.

Case III.—Mr. G——, a clerk, aged forty-five, in enjoyment of good health, is stricken down with an attack of influenza in the early days of March, 1892. Had scarcely resumed his occupation when, on March 26th, he is taken with a violent hemorrhage of the left nostril. Dr. Samuel Logan, his family physician, being indisposed, Dr. F. W. Parrham is called in, and after packing the nostril with absorbent cotton controls the bleeding for the time being, and advises him to consult me. The next morning patient is awakened by a recurrence of the epistaxis, the blood finding its way this time into the throat and other nostril. He comes to my office in a state of great exhaustion, and is immediately directed to the Eye, Ear, Nose, and Throat Hospital, where, with the assistance of Dr. Charles J. Landfried and the resident surgeons, the nostril is cleaned and irrigated with a hot boracic acid solution and rubbed with a twenty per cent. solution of cocaine, as is also the posterior surface of the velum. A septal ridge is found running backward, where it comes in contact with the inferior turbinated body. It is from this point of contact that the blood is oozing. As in Case I., the opposing surfaces are touched with a hot electrode and cauterized until the hemorrhage is stopped.

In this case, to obtain a firmer packing and to obviate the tendency of the gauze to slip back, I made use of a temporary post-nasal plug of wet absorbent cotton, which being larger than the choana was tightly drawn against it by means of the thread kept against the floor of the nostril, and held out through the anterior nostril by an assistant. It is with this wall to work against that I proceeded, as in Case I., to build a continuous antero-posterior packing until the whole nasal chamber was plugged firmly behind and more loosely in front. The post-nasal plug of absorbent cotton is then easily removed, when, by posterior rhinoscopy and retraction of the velum with Voltolini's palate retractor, the packing can be seen nicely and solidly in place. I had formerly made use of it to advantage in cases of intra-nasal operations in children, to whom I had to administer chloroform, with a view of shutting out the blood in the recumbent portion from the naso-pharynx.

No unpleasant symptoms followed the manipulation; at no time was there even a temporary hyperæmia of the drum, nor any fever, nor, in fact, much inconvenience, with the exception that on the third day a strip of gauze found its way into the post-nasal space and slipped down into the pharynx, where it had to be cut through the mouth. This had to be done several times, when, on the fifth day, the remnants of the gauze were removed and the nostrils cleansed and irrigated. No recurrence of the hemorrhage from that date. Patient left the hospital on April 10th with nasal breathing very much improved to what it was previous to his sickness.

Case IV.—Miss C. N——, aged seven, of a decidedly brunette type, has always been a healthy child; had a light case of measles two years ago. Two months after, she received a blow on the right side of her nose with a square block of a toy game of patience, hurled at her by a younger sister. This accident was immediately followed by a light epistaxis, this being the first bleeding she ever was subject to.

As a result of this accident, according to the mother's statement, her nasal breathing became somewhat labored; her nostrils block as if she had a cold in the head, and the secretion of the nose, offensive at times, would occasionally determine an erythematous or eczematous eruption at the entrance of the nose.

January 24th.—The child is taken sick with an attack of influenza, with fever and predominance of catarrhal symptoms, for which quinine and appropriate treatment is administered by Professor E. Souchon, the family physician.

January 27th.—At 5 A.M. patient began to bleed from the right nostril, the hemorrhage seemed to stop after a little while, when all at once, one hour after, the child vomits a large quantity of blood, and continues to bleed for two hours, mostly from behind. When the family attendant arrives he finds that the hemorrhage has stopped spontaneously. The little patient is very pale and weak, but the fever, previously high, has subsided with the epistaxis.

January 28th.—She is comparatively well and plays all day in bed. At night hoarseness and croupy cough.

January 29th.—Fever has returned, and is accompanied with an incessant cough.

January 30th.—The fever, which continues quite high, is reduced with a small dose of phenacetin, administered in place of the quinine.

At 4 P.M. there is a recurrence of the hemorrhage from the same nostril, at first in front, but soon after from the back of the throat, the child swallowing the blood to vomit it in large clots. Upon the advice of Professor Souchon I am sent for, in order to make an examination of the nostril. The child, when I arrived, had moderate fever and a decided laryngo-bronchial cough, no pulmonary complication, but was bleached and very weak. Blood was trickling in the throat along the back surface of the posterior wall of the pharynx.

An anterior plug of absorbent cotton, soaked in a ten per cent. solution of cocaine was inserted in the nostril and secured firmly against the cartilaginous septum, with

no other effect than to perhaps increase the post-nasal bleeding. The whole length of the nostril was then thoroughly cocained with cotton wrapped around a flat applicator, and soaked in the solution. A stenosed condition was found in the posterior half, especially of the lower meatus and region of the inferior turbinated body.

That condition, the age of the patient, and poor illumination made it impossible to exactly localize the seat of the bleeding, beyond the fact that it originated in the rear part of the cavity.

It was stopped only after a careful packing, so far back as seemed advisable, with two strips of iodoform gauze firmly matted down on the floor of the nostril, and built up until the middle turbinated body was reached.

January 31st.—Fever has subsided to return again the next day, when quinine was administered.

February 3d.—Professor Souchon removes the anterior strip of gauze, which was beginning to slip out and was worrying the child. No hemorrhage.

February 4th.—Although very weak, patient is brought to my office; I then removed the deep antero-posterior plug of gauze and proceeded to a thorough examination of the nostril with a bright reflected sunlight and a five per cent. solution of cocaine. Was quite surprised to find a marked osteo-cartilaginous septal ridge impinging, more particularly in the back of the nostril, on a turgid but comparatively pale inferior turbinated body, on which cocaine seemed to have little or no effect.

From that day up to February 21st patient seemed to be doing fairly well—tonics are administered and highly nutritious food taken. She is brought hurriedly to my office by her grandmother's nurse, as the hemorrhage has returned again, mostly from behind. This is stopped with the galvano-cautery applied over the crest of back part of ridge, and also opposite surface of superior turbinated body.

For greater safety the nostril is again packed with three continuous antero-posterior plugs of iodoform gauze. A slight fever and watery oozing followed for two or three days after this procedure, probably as a reaction of the galvano-cautery. The slough was eliminated on the eighth day, when the plugs are removed and the mother is instructed to keep the child's nostrils cleaned and properly disinfected.

At no time did any unpleasant symptoms follow the local treatment, but the weakness of the child was so pitiable, her complexion so waxy, the anæmia so acute, almost pernicious, I may say, that although the urine revealed nothing abnormal, I advised that an examination of the blood be made, the spleen and liver examined, and the child sent out to the country as soon as possible, regardless of any risk that might be taken by a return of the hemorrhage, which, in fact, never returned.

April 24th.—Upon inquiry the parents reported subsequently a progressive aggravation of this acute hydræmia, the last phase of which is marked by an absolute anorexia and incoercible vomiting. Five or six physicians have succeeded each other in the management of the case, but to no avail.

May 2d.—The family has finally consented to the removal of the child to the country, but with little or no hope of recovery, as the child, from what the father relates to me to-day, is considered very low.

May 8th.—Patient died, thoroughly exhausted from intense anæmia, and without, as her last attendant, Dr. Bayou informs me, having presented the slightest indication of any organic disease.

In reviewing these four cases the following features are most noticeable.

1. The association of these epistaxes with influenza, whether, as in Case IV., the hemorrhage takes place in the midst of an attack, or, as in the other three cases, it occurs during the decline or convalescence of the disease.

2. The coexistence in those cases of severe grippal epistaxes of a previous condition, in the bleeding nostril, of an obstructive character, localized in the rear part of the nasal chamber.

3. The danger of post-nasal plugging, which should be abandoned in the treatment of most, if not all, such cases, in favor of a much more simple, more effective, and safer procedure—the continuous antero-posterior packing, with or without the preliminary use of the galvano cautery.

Hemorrhagic complications have been sufficiently frequent during the last epidemic of grippe to justify some observers in classifying such cases under the name of "hemorrhagic influenza." In view of the fact that acute coryza seems to be one of the most constant of the manifestations of influenza, it is to be wondered at that nasal hemorrhage has not been reported oftener in this disease. Its frequency has varied materially in different epidemics. We find that during the outbreaks of 1411, of 1580, of 1727, and of 1837, the occurrence of epistaxis was considered as a favorable symptom, while in 1743, according to Des Sauvages, the appearance of the nasal hemorrhage very often preceded or accompanied a fatal termination.

In 1782 (in Lunenburg) epistaxis would seem to have played the most important part in the symptomatology of the disease. As a matter of fact, epistaxis is very generally mentioned as a symptom in most all old reports of epidemics of grippe.

In 1889–90 several cases of epistaxis were observed by Dr. Paul Tissier, in the service of Professor Proust, at the Hôtel Dieu, of Paris. M. Comby cites examples (eighteen cases out of two hundred and eighteen) of repeated nasal hemorrhage in children. Jacobi says it is exceptional. Lublinski has observed in influenza a hemorrhagic rhinitis; A. Ruault and Mesnard have also seen epistaxis in the course of influenza. Herzog states that he has often met with that symptom. Nemier asserts that epistaxis at times shows the implication of the nasal fossæ. Haberman, Robinson, Cheminalde, and others call attention to this symptom, the bleeding in some cases being quite profuse and recurring at different times.

Holtz mentions the case of a strong and healthy man, thirty-six years of age, whose life appeared to be at one time in danger as a result of this complication. Dr. M. Litten, in the great recent work on influenza, published by the Society of Medicine of Berlin, writes, in the chapter on Symptomatology that "epistaxis was quite common during the epidemic (1889–90); it returned in cases of relapse, and was sometimes so profuse that it was considered uncontrollable by the observers." Sokolowski, after mentioning that he has observed epistaxis in the course of different forms of influenza, adds, "The only complaint, even of two patients, was the profuse epistaxis, which lasted for several days. They applied for help on account of persistent nose-bleeding, from which they never before suffered."

These, with a very few others, are, as far as my knowledge and researches go, the few mentions made by observers of that manifestation. We must, therefore, admit that epistaxis, while not a very constant symptom, is still frequent enough in the various epidemics of influenza of which we have the narrative.

As to the time of appearance of grippal epistaxis, Tissier and others, like Robinson, state that it has generally shown itself, at least in the epidemic of 1889–90, as an initial symptom. Antony has seen it recur one month in the case of a soldier. In my four cases the nasal hemorrhage took place once in the course of the attack (Case IV.), and in the other three cases it must be considered as a sequela.

No late observer, outside of C. Fiessinger, has attached to the epistaxis any such influence as reported by the old writers on the evolution of influenza. He says that repeated epistaxes in the beginning or during the course of the disease seem to lead rapidly to a favorable termination. Some authors mention that, as in Case I., it has at times relieved a very painful symptom, viz., cephalalgia, or reduced the fever for the time being, as in Case IV.

Before discussing the question of the pathogenic diagnosis of these epistaxes and the mechanism of their pro-

duction, permit me, gentlemen, to insist on the fact that in none of my cases did a careful examination reveal any visceral taint or any diathetic alteration, nor was there in the history of the patients any reference to hemorrhage, with the exception of Case IV., previous to the attack of influenza. I am, therefore, justified in excluding from the pathogeny of these epistaxes such etiological factors as organic disease of the heart, chronic hepatic or renal alterations, hæmophilia, and many other general affections, which, we all know, will determine at times very serious nasal hemorrhage. I have often met with cases of this kind, two of them in connection with influenza, which I have studiously avoided to include in the above-mentioned ones, as besides influenza other well-known causes could be incriminated. Those observers who have, like myself, noted this complication in connection with grippe, have all been very reticent on its mode of production. As to myself, without pretending to link these hemorrhages to an absolutely defined pathogenic formula, I am inclined to believe that they reflect the impress of the infectious character of influenza, associated with the otherwise secondary element of stenosis. These hemorrhages would, according to that view, be due to the presence of pathogenic micro-organisms in the blood (if this etiology is the correct one) introduced through the respiratory tract. They would give rise to certain intra-nasal vaso-dilatations, which, in the already stenosed parts, would be more accentuated. It is possible that the microbes may generate toxines, which, through the nerve-centres, exert a direct irritant action upon the vaso-motors at those weak points. The general blood dyscrasia would, therefore, like in other infectious fevers, have its share in the production of these epistaxes. These views I must, however, admit are as yet purely theoretical, and must remain as such until the specific germ of influenza is discovered and reproduced to the entire satisfaction of bacteriologists.

While admitting the primary influence and importance of the grippal infection in the production of these epistaxes, which is, by the way, the only manner in which to account for other hemorrhages, as reported in the last epidemics of influenza, I cannot overlook another feature as presented in my observations, viz., the fact that the bleeding invariably proceeded from a more or less stenosed nostril; the roomier nostril, free of septal deformity, played no part in the production of the hemorrhage. As to its seat, it was clearly defined by rhinoscopic examination; in three of my cases it did not originate at the antero inferior part or at the centre of the quadrangular cartilage, the point of election in the great majority of cases, as established by the researches of Chiari, Voltolini, Baumgarten, Kiesselbach, Calmeltes, and many others, and as confirmed by daily experience. I therefore feel justified in considering the stenosis as a factor in the production of the hemorrhage, to this extent at least, that it has allowed the intra nasal vaso-dilatation due to the influenza to so intensify the obstruction as to cause an attrition of the opposing surfaces, and subsequently an erosion of the parts, especially over the crest of the projecting septal spur. On this point I can only agree with Dr. Bosworth, as against the views of Jurasz and others, when, referring, it is true, to the anterior part of the nostrils, he writes: "Slight deformities of the septum are probably the cause and source of an epistaxis more frequently than any other lesion met with in the nasal cavity, the apex of the projecting portion becoming the seat of a slight erosion, probably as the result of attrition by the dust-laden currents of the inspired air."

A few words now, gentlemen, before closing my remarks, on the question of post-nasal tamponning, which, as demonstrated in Cases I. and II., and although performed by skilful surgeons, has evidently led to very unpleasant and very dangerous complications. I would certainly not mention this antiquated procedure before a meeting of specialists, but for the fact that it is unfortunately too generally advocated in text-books on general urgery, and, I regret to say, even by some writers on our specialty, like McBride, W. Spencer Watson, and others. As to myself, I firmly believe, with Chatelier, that there are very few cases, if any, of epistaxis of such a character as to compel us to revert to post-nasal plugging. Leaving aside the hemorrhages of grippal origin, I have had to attend six other cases of very serious epistaxis from different causes. In all of them I have been uniformly successful in arresting the hemorrhage by the method of continuous antero-posterior packing, and in none of them have I had to register any unpleasant complications. I would further emphasize the comparative innocuity of the method by stating that I have very often resorted to this mode of dressing after prolonged intra-nasal operations in the posterior half of the nostrils, without any untoward effect directly attributable to the method, notwithstanding the fact that the gauze was left in place several days.

In order to insure this immunity from complications, due attention must be paid, 1st, to the preliminary disinfection of the nostril; 2d, to the packing material employed, strips of iodoform gauze being the best, as suggested several years ago by Fletcher Ingalls; 3d, to the proper anæsthesia of the nostrils with a solution of cocaine, which is also a good hæmostatic; 4th, to the continuity of the packing, which allows of no accumulation or retention of blood or of secretion apt to undergo decomposition.

In concluding this contribution, and judging from the serious character of nasal hemorrhages in these four observations, I could infer, as against the opinion of most other observers, that epistaxis of grippal origin presents an unusual gravity; do not understand me, however, as formulating such a diverging opinion. I can only say in explanation of this gravity, that I must have met, as we all do in practice, with an unlucky series, and that such cases must be considered exceptional in the history of epistaxis of grippal origin.

QUESTION OF MECHANICAL VIOLENCE IN THE TREATMENT OF DIPHTHERIA.

By J. R. CULKIN, M.D.,

ROCHESTER, N. Y.

This disease, which has for centuries past called forth the best thought and efforts which the profession could bring to bear against it, is still able to baffle us as regards its etiology and as to the best method of treatment. Of a certainty remedies enough have been proposed, lauded, and sunk into oblivion, after having been used for a brief period. Powerful germicides have been used to destroy the germs, as corrosive chloride of mercury, carbolic acid, salicylic acid, and a number of other products of advanced chemistry; digestive agents, such as pepsin, pancreatin, papayotin, and many others to digest the membrane, and cause it to fall from the throat an inert digested mass, also remedies to sweat it off, as pilocarpine and many another variety of remedy which are well known to you all, have been used on some hypothesis, or fact if you will, and found to fail.

During all this looking for a specific to destroy the germ or ruin his habitat by digesting it away from him, or again with our sweating remedies to remove it from the tissues, it seems to me that many lose sight of the fact that while we are dealing with a germ which we wish to destroy, we are also dealing with a being which is worthy of every effort on our part to preserve.

In order to render clear the points I wish to make in my paper I will briefly review the pathological conditions found in the nose and throat in a case of diphtheria of the same. Roughly speaking we may divide the invasion into three types:

1. A mild case, when with a moderate amount of redness and œdema of the throat we have a thin friable membrane extending over the tonsils. The mucous membrane under it is congested, infiltrated with leucocytes, and its epithelial covering is dead and incorporated in the false membrane. A removal of this membrane even ever so gently is apt to leave behind a few bleeding points and a surface denuded of epithelium, which forms an excellent soil for the implantation of the germs.

2. When the necrotic process has gone deeper and involved the mucous membrane proper, causing it to be incorporated with the false membrane. The false membranes in this case are thicker, more deeply imbedded and hard to remove, and if removed by violence leave a bleeding ulcerated surface, which generally becomes covered again with false membrane, and the structure under it undergoes necrosis, leaving a deeper ulcer than we had before. The torn and bleeding surface forms an excellent soil for the implantation and growth of the bacilli, and the lacerated vessels a ready channel for the absorption of the poisonous ptomaïnes.

3. When we have a deep sloughing ulcer covered with dark tough membrane formed by the deeper structures of the tissues. The membrane is often dark from hemorrhage into its substance and tough, as it contains connective tissue and mucous membrane in its mass. The parts surrounding this necrotic area are very œdematous and infiltrated with leucocytes. The epithelium is at times dry and shiny, but generally covered with pus and stringy mucus. The epithelium is already dead, or so far advanced in the process of the coagulation necroses that it will soon fall off, leaving a surface raw and ready to be infected. This condition of the epithelium and the mucous membrane surrounding the already infected area is one of great importance to consider, and on it hinge the remarks which I wish to make in regard to mechanical violence by the use of the swab, or in efforts to remove a membrane.

I might here with propriety speak of a type of case which is not so common, but is, nevertheless, very fatal in its effects. It is when we have with but little œdema or redness, a punched-out ulcer of the tonsil, with a thin but very closely adhering membrane on its surface. It is slow in its progress, but sure to proceed by a gradual widening and deepening process to a fatal termination. It does not seem to cause sloughing *en masse* so much as it does ulceration. It would seem to one that you would be able to destroy it at once by strong carbolic or other caustic, but often after each application, no matter how thorough, it gets deeper and wider, and ends in death, slowly. A point in its pathology is the fact that we have little or no glandular reaction against it, and the lymphatics of the neck are not at all, or very little, swollen by the process. It would seem rational to suppose that the inflammation of the glands stops the circulation of poison-bearing lymph on its way to the blood; but in these cases the glands not being inflamed, the lymph goes unobstructed to the blood, bearing the poisonous ptomaïnes into the general circulation.

The fact is noticed by many writers on diphtheria that in diphtheria of the tonsils we have little or no lymphatic enlargement, but in the class of cases of which I speak, it is very conspicuous by its absence.

I have had four of these cases. The first two ended fatally, while I was treating them with caustics, stimulants, tonics, and so on. The third I resolved to treat more in a general way by antiseptic sprays, stimulants, and tonics, but it did not improve, and counsel taken resulted in my reasoning being overruled and caustics and the swab being used, with the same result as in the previous cases, viz., a rapid increase of the ulceration and a speedy termination of the case. The fourth was like the third, except that my consultants both gave a favorable prognosis, only to see the child die in two days under a vigorous course of treatment.

The constitutional symptoms in these cases are slight at first, with but little fever or pain and no restlessness, but day by day the patient gets weaker, with a gradual acceleration of the pulse. There was free perspiration in all of these cases.

Of the false membrane itself, W. Gilman Thompson says: "Diphtheritic inflammation is characterized by the production of fibrinous exudation. The stroma of the mucous membrane is filled with more or less disintegrated leucocytes, pus, and fibrin, which also appear on its free surface. There is coagulation necrosis of the epithelium, which is shrivelled and distorted in form, with indistinct nuclei or none at all. The false or pseudo-membrane is composed of flaky necrosed epithelium, disintegrated

leucocytes, pus, fibrin, bacilli in varying relative amounts, and sometimes red blood corpuscles. The mucous membrane beneath is more or less necrotic, and the sub-mucous layer is necrotic in bad cases.

"There is hyperæmia and often tumefaction of the surrounding mucous membrane which secretes a muco-purulent secretion. The redness of the surrounding area is often distinctly localized."[1] On the same page he remarks: "Several successive membranes may form on the same site. This is particularly the case when they have been forcibly stripped off."

The restoration of the epithelial covering of the mucous membrane takes place, of course, from the epithelial cells surrounding the ulcerated area or from those not destroyed by the diphtheritic process.

Lesions of the mucous membrane undoubtedly aid in the spread of the virus, and hence the injurious effects of forcibly stripping off the false membrane and exposing the raw, bleeding surface.[2]

The majority of the profession believe that diphtheria is a germ disease, and that the Klebs-Löffler bacillus is probably the cause of it. The experiments carried on by various bacteriologists confirm this belief, but they are not as yet numerous enough to enable us to say that it is so beyond doubt.

The portion of the profession who are still in doubt as to the etiology of the disease, forms a very strong part of it. Ptomaïnes have been isolated from the false membrane and from cultures which show marked poisonous effects, and some claim for them the ability to establish immunity to diphtheria.

But whatever our belief may be as to the nature and etiology of diphtheria, we all recognize it as an infectious and contagious disease whose effects on the system are very marked, whether primary or secondary, and that in its local manifestations it is very virulent and prone to establish itself wherever the tissues are devoid of epithelium.

That we see many die from its invasion of the larynx with but slight systemic manifestations, and many again die from its systemic effects with but few local manifestations.

In considering the local effects of mechanical violence to the throat, we will do well to have in mind the following facts:

1. That we probably have in the throat pathogenic germs ready to invade every area laid bare of epithelium.

2. The poisonous ptomaïnes are more readily absorbed by a raw and bleeding surface than by one covered by epithelium.

3. That a portion of the involved tissue is already necrotic, another portion nearly so, and the area surrounding those portions is acutely inflamed.

4. That it is impossible to render by any means known to us a diphtheritic throat antiseptic.

A glance at the above statements will, I think, show good reasons to anyone why all violence to the throat should be avoided in treating diphtheria, for I heartily believe that the natural process of separation of the sloughs from the throat is the best and most conservative way.

To make it clear: Take a case in which we have a membrane which looks loose and seems easily removed, and attempt to take it away with a swab, and if you succeed you will in many instances do so at the expense of bruising the tissues, scraping off the epithelium, and will leave behind you a surface ready to be infected again; or if you do it to make an application of your favorite remedy, I ask you what remedy applied with a swab can reach into each recess of the throat, penetrate a mass of pus and mucus and then kill all the germs to be found there? No remedy will do it, for germs enveloped in mucus, or sunk deep behind the tonsils, or down in a membrane, will laugh at your efforts to destroy them. Of a certainty you kill a few, but not enough to compensate for the damage your swab has done.

Many times applications are made as thoroughly as can be to the throat with powerful germicides, which in a test tube are sufficient to destroy the life of the germ, but in the throat your swab is quickly enveloped in mucus, and you only succeed in irritating the throat, giving great pain to your patient, causing him to vomit and to sink back in bed in every way worse for the interference.

If a surgeon wishes to cauterize a chancroid, does he not carefully wipe it dry, expose each little fold so that he may reach every part? Even then he will fail at times with the most powerful caustics. What effect would he expect if he left it covered with pus and mucus, and simply drew his swab across it? None, surely. What good reason then can be given for picking up a poor child every hour, forcibly opening its mouth, causing the glands at the angle of the jaw to be compressed, pressing into its throat a swab laden with a germicide, and wiping it about, withdrawing it covered with mucus, pus, and perhaps a little membrane, and leaving the throat raw and bleeding. Your child has struggled violently, suffered much, and vomited that little nourishment which would have sustained its strength and enabled the system to resist the ulcerative process in the throat. This is done hourly, day and night, and the little patient gets weaker and weaker, and the diphtheria spreads rapidly, and what wonder is there when we think of its struggles, its vomiting, and the pain and suffering caused by the application. We all know full well that empty lymph-channels will absorb poison more readily than full ones, and can we wonder that a child made to vomit eight or ten times a day has hungry lymph-channels and little resistance to offer to the inroads of the disease?

The rational side of this question is often overshadowed by the desire to destroy a bit of membrane and a few germs. No one appreciates the work done by the bacteriologists more than I do, but believing that by the means at our disposal we are unable to destroy the bacteria, I object strongly to violence being done to the throat with that end in view. Give the system but a chance to fight, and nourish it by every means known to you, and many cases which are now fatal will be saved, and many cases of a mild character will speedily get well, instead of being aggravated into virulent cases by our mistaken and inefficient efforts at a cure.

If we have to deal with threatened gangrene in a flap after amputation for crushed wound, we do not every hour or half hour squeeze it and apply all sorts of drugs to it, but rather we handle it gently, disturb it little, and do as little violence to it as possible. In the throat we have tissues threatened with gangrene, and are we justified in using a swab on them every hour or half hour and inflaming them past recovery in the hopeless task of killing all the germs.

Time and again have I been able to convince myself of damage done by this swabbing of the throat, and have seen surfaces which had been left raw and bleeding covered in the course of an hour or so with membrane. Then, too, I believe that the swab often carries to parts not infected shreds of membrane and infects them. When one depresses the tongue in a case of diphtheria and sees at its base the epiglottis red and swollen, and then puts in the swab and wipes it across the membrane, and, no doubt, touches the epiglottis with the infected swab, he can well have doubts as to the harmlessness of the swab.

In dealing with a case of septicæmia from any cause how careful we are to conserve the energy of the patient, to improve his nourishment, and to disturb him as little as possible; and rightly so too; but in these cases I have often seen a wanton waste of the vitality of a little child by efforts to cleanse the throat. If these efforts could in the nature of things be effective I would not complain, but I do not think they can, as a rule, be so; so I take a stand against any violence being done to the throat in

[1] American Text-Book of the Theory and Practice of Medicine, vol. i., p. 379.
[2] Loc. cit., p. 380.

diphtheria. No matter if it is to establish a diagnosis, make an application, or remove membrane, except when hanging loose.

W. Gilman Thompson says "that it takes the best judgment of the physician to avoid the danger of exhausting the patient's strength by too energetic local treatment, and the even greater dangers of sepsis and occlusion of the air-passages by rapidly extending false membrane." Too much thought cannot be given to the first part of this quotation, for while we all insist that we do everything possible to preserve the strength of the patient, we do many things inconsistent with the preservation of the same.

Many physicians never use the swab at all, and I believe that the majority do not, still, my dealings with brother practitioners show me that many use it at times and others as a routine practice. A little over a year ago, in consultation with a professional man, I was persuaded upon in a moderately severe case of diphtheria to use a saturated solution of sodium bicarbonate every hour, only to see the membrane spread rapidly under its use and to see the child die—I cannot say from the effects of the swabbing, but certainly the end was hastened by it.

Another case where iodoform and boric acid were used after cleansing (?) the throat well with a swab, the result was that in eight hours the throat was completely covered with false membrane and the child died. And family and doctors struck up the old chorus, "Everything possible was done."

I appreciate as much as anyone the need of disinfecting or cleansing the throat, but I think it can better be done with an atomizer throwing a coarse spray of mild disinfectant to flush out the throat. And I am strongly convinced that hourly or half hourly applications do more harm than good, except in cases where a child is old enough to take the treatment without any resistance. If they resist, every two hours is frequent enough in the day, and two and a half or three at night.

In the nose I use a mild antiseptic and flush it out well with a douche pot and rubber catheter, doing it thoroughly and then giving the child a chance to catch its breath before I go germ-hunting again.

The effect on the minds of the friends of your little patient when they see you make a local application to the throat is very marked, and when they see you remove a piece of membrane from the throat they are apt to be overjoyed, just as if the membrane were merely a foreign body; but do not let their clamor for something to be done to "cut away" the membrane make you forget the lesson which scientific pathology has taught you in regard to the ability of the remaining germs to infect any area laid bare by violence. I think that many are led to adopt this violent method of treatment as a result of an ofttime repeated and strongly stated desire for active treatment. But we should be above all such influences.

Much might be said of the harmful effects of the action of strong caustics or disinfectants on the throat and nose, but that would prolong my paper beyond its intended limits.

Many authorities might be cited on both sides of this question, but I do not deem it needful in such a paper as this to lumber it up with references from all sources.

If I have rendered clear my position in regard to the harmfulness of the swab and undue activity in treating diphtheria, of the effect of harrowing the throat and laying bare a fertile soil for the propagation of germs and the extension of false membrane, of the exhausting effects on the constitution of the oft-repeated disturbance which results from making local applications, and of the crying need of preserving the strength of the patient, I am content.

414 Lyell Avenue.

It Is Stated in a German paper that more than twice as many people died in London this winter from influenza as died in the same city in 1843 from cholera.

LOOKOUT MOUNTAIN, TENNESSEE, AS A HEALTH-RESORT.

By W. A. DEITRICH, M.D.,

LOOKOUT MOUNTAIN, TENN.

During the spring of 1888, while practising my profession in northern Indiana, it was my misfortune to contract pulmonary tuberculosis, for which I consulted the late Dr. Joseph P. Ross, of Chicago, and through his advice I sought a residence on Lookout Mountain. A full description of my case was published in the *Journal of the American Medical Association*, of August 16, 1890, but suffice it to say that I have entirely recovered my health.

Lookout Mountain has been known in history ever since Hooker fought his famous "Battle above the Clouds," but farther than this scarcely anything has ever been said of it, and little is known of it as a health-resort by our northern brethren. The mountain rises abruptly from the Tennessee River, until it attains a height of seventeen hundred feet above the river, and two thousand two hundred and eighty feet above sea-level. Lookout stands alone in its majestic beauty, being separated from all other mountain ranges by a wide and fertile valley. The top, or plateau, is an undulating surface, beginning with a point at its northern extremity and gradually widening out as it runs southward, until it reaches a width of a mile or more. It extends across the line into Georgia, but it is only of that portion of the mountain lying within the borders of Tennessee that I shall speak, as it is the only part that is of easy access. The greater part of this plateau comes to an abrupt end where the rock seems to have broken off precipitately and left a perpendicular bluff several hundred feet high. The soil is light and sandy, absorbing moisture so rapidly that within a few hours after a rain a person can go out walking without fear of getting damp feet. A large part of this plateau was cultivated previous to our civil war, but since then it has grown up in primitive forests of pine and oak, with the former predominating.

It is impossible to give a pen picture of this grand old mountain by which any effort of the imagination can form an idea as to its beauty and grandeur. To say the view from its top is grand would not express it. It is not only grand, magnificent, sublime, but also very entrancing. The scenery is varied from every point of observation, and to the lover of nature are presented views of which he will never weary; and this of itself will urge invalids on to keep out of doors and ramble from place to place. From its lofty summit seven different States can be seen, and with the city of Chattanooga lying at its base, with its fifty thousand souls, and ten different trunk railroads centring there, it produces a scene not to be found elsewhere. Its beauty can only be appreciated by the eye of the beholder.

Unfortunately, the meteorological records (except its temperature) have never been taken until within the last year, but comparing what we have with the observations taken in the city of Chattanooga, we can form a fairly good estimate. The mean annual temperature is 54° F., with a mean annual range of 17° F. During the winter the temperature seldom falls below freezing, and only once during the past five years has it fallen down as low as 2° F., and that last winter, while only fifty miles north of us it registered 12° F. below zero. During the summer the temperature has only risen above 88° F. five times, and that occurred the past summer. The snowfall has been almost *nil*, with the exception of once last winter, when there was a fall of about nine inches. The average number of clear and fair days during the entire year is twenty-four in each month. It is impossible to give the rainfall, as no exact data have been kept of it. The average relative humidity can only be estimated from that of Chattanooga. The United States weather observer there says it is at least five less than that of the city, and as it is 71 in Chattanooga that of the mountain must be 66 or less. The air is relieved of a great deal

of its moisture as it is wafted across the mountain-ranges surrounding Lookout on all sides, thus giving us a dry atmosphere. It is free from all micro-organisms and impurities, as there is nothing here to contaminate it. Sunshine is abundant, and gentle breezes are always blowing; sultry days and wind-storms are unknown. The air is invigorating, it having neither the debilitating heat of the Southern clime nor the severe storms and cold of the Northern to affect us.

Dr. Wight, after a thorough investigation, states that consumption has never been known to occur among the natives of the mountain. Malaria seldom if ever occurs, at least I have never seen an original case of malaria or consumption during my five years' residence here; but, on the contrary, I have carefully watched the progress of a great many consumptives who came to Lookout with the hope of improving their health, and if possible receive a cure. With very few exceptions, everyone who sought a residence here was either benefited or cured. The most of those who received no relief were so far advanced with their disease that it was utterly impossible for them to be benefited anywhere. Those of an acute character naturally found the quickest relief, while those with the so-called fibroid phthisis improved slowly; but with proper care, diet, and exercise, everyone (unless too far advanced) would find almost immediate relief, and if they remained long enough a cure would result in the great majority of cases. Consumptives, after visiting some of the other health-resorts, such as California, Colorado, Texas, and Florida, and receiving no benefit, have come to grand old Lookout, and their improvement soon became apparent. I recall, for instance, the case of a young gentleman, a professional brother, with phthisis, who had spent some time in Colorado and New Mexico seeking relief, but failing to find it he returned home, as he thought, to die. While at home he was advised by Dr. Ross to try this place. He did so, arriving here about January, 1889, and remaining until the following August, when he again returned home to all outward appearances a healthy man, but still having a slight induration in the lung. He then went to California to practise his profession, but after residing there a year or two his trouble had increased so far that he died. I could cite numerous other cases like this, some that remained long enough to receive a complete cure, others, after receiving a partial cure, would return home thinking they could not remain away from business any longer. The one great trouble with consumptives going to a health-resort is that they will not remain long enough; as soon as they are on the fair road to recovery they become anxious to return to their families, friends, and business. When invalids are sent away from home and relatives to seek a new climate, they should be instructed to remain (providing they improve) until their attending physician says their health is entirely restored.

Other diseases that are benefited by a residence on Lookout are insomnia, nervous prostration, asthma, bronchitis, and the enteritis of infants. Children are frequently brought to the mountain during the summer months with cholera infantum, so sick that the physicians say they could not possibly live more than a day or two in the city; yet, as if by magic, they commence to improve almost immediately after reaching its summit, and that with very little medicine. Only a few weeks ago Dr. Bowen, of Paris, Ky., brought his baby suffering with enteritis to the mountain, carrying it on a pillow, and not thinking that it could possibly live. The child soon began to brighten up and feel better, and a few days ago they left the mountain with a healthy baby, and feeling very enthusiastic on the climate of this place.

Lookout Mountain is accessible by rail from every point of the compass. It has an incline and standard gauge railway connecting it with Chattanooga, thus giving quick and easy access to that thriving city. Dr. J. A. Robison, of Chicago, says: The ideal requirement for the treatment of consumptives is a combination of all the requisites of a perfect climate, and also the opportunity to enjoy city life with its attendant evidences of civilization. He further says the only locality where there is a possibility of such a combination is Lookout Mountain, Tennessee.

It is an all-the-year climatic resort, and has the advantage over other resorts in being within easy reach of all Northern and Eastern cities. The water-supply is abundant and as pure as can be found, consisting entirely of mountain spring water, either freestone or chalybeate.

The facilities for entertaining invalids and tourists were very limited until a syndicate of New Englanders purchased Lookout Inn and opened it for the winter as well as summer. The inn is a magnificent structure, three hundred and sixty-five feet long, with wide verandas running around on three sides, the southern one being enclosed in glass. The rooms are large and commodious, well ventilated, and every one is an outside room. They are either heated by open fireplaces or steam. Especial care has been observed in putting the building in the best sanitary condition possible. Its cuisine is such as will tempt the appetite of the most fastidious.

Progress of Medical Science.

Bacterial Poisons.—No subject at the present day can be more interesting, and yet but little is known respecting bacterial poisons. The work of Gamaleia ("Bacterial Poisons," Detroit, 1893. American Edition, translated by E. P. Hurd, M.D.), despite its literary merit and the great array of facts, is a little disappointing, and one really wonders on reading this book that so much could be written, and so little information given. The first experiments of Seybert, Gaspard Stich, Magendie, Dupuis and others established the symptoms and lesions of experimental septicæmia. Panum showed that it is produced by a chemical poison: Bergmann and Schmiedeberg determine this poison to be an alkaloid sepsine. This result marks a first stage in the investigation. Down to about 1870 Panum's views were almost universally prevalent. Bergmann's sulphate of sepsine, obtained in crystalline form from putrid infusions, was believed to be the veritable putrid poison that causes septicæmia, and the action of microbes was ignored. Sepsine was thought to be a ferment, acting in infinitesimal quantity. It was, however, soon found to be impossible to ascribe all the forms and symptoms of septic poisoning to sepsine alone, and that the poisons produced by putrefaction were many and various, according to certain conditions; and there was for many years a contest between the chemical and the vitalist doctrines, ending in the victory of the latter. Liebig's hypothesis that the soluble ferments are albuminoid matters in process of decomposition, was overthrown by Pasteur, who demonstrated that fermentation and decomposition do not exist apart from the life of organized ferments. Moreover, the contagionists were soon able to prove the fallacy of the chemical doctrine by showing that certain microbes separated from their morbid products were able to produce determinate diseases. At the same time was established the fundamental notion, proclaimed by Cohn, of the specificity of bacteria, and bacteriology took its place among the sciences. The vitalist doctrine was not, however, in absolute contradiction to the chemical; and Panum has the merit of having understood the possibility of reconciling the two theories. He affirmed, that "it is incontestible that the putrid poison is chemical, but that it might be produced by a microbe, even a determined microbe. In diseases, both the pathogenic microbe and the production of the poison by the microbe, may play their respective parts." These words, uttered in the infancy of bacteriology, have been shown to contain a profound truth. The discovery of ptomaïnes by Selmi, Brieger, Gautier and others marks the next stage in progress. These discoveries date from about 1870. The list of cadaveric alkaloids naturally resulting from putrefaction of albuminoids was soon quite large; and the query was soon raised whether it might

not be dangerous to eat flesh, or even fish, and other animal products, for fear of ptomaïne poisoning. At least, invalids with weak digestive functions were warned of the danger. Later on, a careful criticism of the work of Gautier, Nencki, Brieger and others justified looking with suspicion on their different methods of extraction of ptomaïnes. There is even warrant for believing, as Gamaleia shows, that these methods were likely to create artificial products which did not pre-exist in the albuminoids analyzed. A part of the work of these experimenters will still stand; but the spontaneous formation of ptomaïnes is not so constant a phenomenon as was taught, and the microbial poisons are not ptomaïnes. As for the typhotoxine of Brieger, Bassi has shown that it does not pre-exist in the cultures of the typhoid bacillus; and Salkowski has never been able to find the peptotoxine of Brieger in the products of gastric digestion; in fact, Bouveret and Devic have proved this supposed ptomaïne to be "an artificial product which is formed at the expense of albuminoid matters by the combined action of HCl and alcohol." Roux and Yersin, as a result of their experiments on the poison of diphtheria, conclude that by all its reactions the diphtheritic poison resembles diastases, and none the less by its intense activity in infinitesimal doses. Gamaleia, after a somewhat exhaustive examination of the whole subject, and with the help of researches of his own, concludes, "that the toxic action of the bacteria is not linked to their fermentative action; it does not coincide with any known diastasic action." The microbial poisons have been supposed to be "secretions;" nevertheless, this comparison with secretions accounts but superficially for the facts. "First, there are certain pathogenic bacteria which produce such diseases as tuberculosis, cholera, and charbon, where we do not find any toxic secretions. Then, again, even the production of poisons in diphtheria and tetanus has a very superficial correspondence to a secretion. In fact, the quantity of these poisons in the culture liquids does not grow proportionately to the development of the bacteria themselves. On the contrary, an attentive observation reveals the following facts: At the very first, and at the most active moment of the life of the microbes, the liquid of culture is acid, and devoid of all toxic power. Later, when the bacteria have ceased to multiply and are deposited at the bottom of the culture flask, the liquid becomes alkaline and very highly toxic. Its toxicity augments progressively with the duration of the sojourn of the bacteria in their alkaline liquid of culture." The explanation of this fact he finds very simple: "The poison is contained inside the bodies of the bacteria, and is extracted slowly by the alkaline liquid in which they are macerated."

We have not time to pursue the subject further, and must refer those interested in the subject to the treatise itself. In short, Gamaleia believes that the microbian poisons "are the results of the creative syntheses of the bacteria, and come from their bodies. "Thus is again confirmed our hypotheses respecting their chemical nature, which identifies them with the constituent parts of the nuclei of cells—the vitellines and nucleines. The toxicity of the microbian bodies may have also a teleological signification explicable from the point of view of the struggle for existence and of natural selection; for the toxicity of the bodies of bacteria may be useful to them as a means of preserving them against aggressors which would devour them."—*Boston Medical and Surgical Journal.*

A New Physical Sign for the Early Diagnosis of Croupous Pneumonia.—Dr. F. H. Morison, writing in *The Lancet*, refers to the difficulty of the early diagnosis of pneumonia in children, and quotes Dr. Francis Moinet, in "Keating's Cyclopædia of Diseases of Children," who says: "In not a few cases no satisfactory results are obtained by auscultation and percussion until a comparatively late period, owing to the limited extent of the affected region and its position in the centre of a lobe surrounded by healthy lung tissue." In several cases recently seen, where the general symptoms of pneumonia were present but none of the ordinary physical signs, Dr. Morison adds, "I have discovered what I am venturing to describe as a new physical sign. On careful auscultation of the chest I have heard jerky expiration over a limited area, and on noting the position of this area have found developed in it subsequently the usual signs of pneumonia. This jerky expiration is the first physical sign developed, and can be heard soon, if not immediately after, the rigor, before dulness or crepitations appear. It is much more distinct in children, but I have also heard it in adults."

The Treatment of Tic-Douloureux.—Dr. Jarre read a paper before the Académie de Médecine de Paris on September 5th on the subject of tic-douloureux, in which he attempted to establish on a definite basis not only the pathology and mechanism of production of this painful affection but also the treatment, and he detailed the lines which he had adopted. He maintained that cicatricial lesions of the nerve were the cause of a large majority of the cases, and that the treatment consisted in attempting to remove the cicatrices. As a rule these lesions were situated in the alveolar region at the terminal extremities of the nerves. The most common causes of the cicatrices were chronic alveolar-dental inflammation and conditions brought about by the faulty development of the lower wisdom teeth. The treatment indicated in such cases is to remove a portion of the alveolus, together with the cicatrix which it encloses. The operation is best performed in three stages: firstly, the mucous membrane and periosteum covering the portion of the alveolus which is to be resected are turned aside; secondly, the piece of bone is removed; thirdly, the surface of bone exposed is well scraped. The wound is then washed out and dressed with a pad of cotton-wool soaked in an antiseptic solution. The immediate results of the operation in Dr. Jarre's patients were at first a diminution in the number of attacks of pain, and finally, in four or five days, a total cessation of the symptoms. Ten cases, in which all other methods of treatment had been previously tried without success, completely recovered after this operation.

The Extra-uterine Fœtus.—The generally accepted statement that the fœtus whose evolution has taken place under the perilous conditions of an ectopic gestation is usually deformed, and would therefore be a potentially undesirable member of the community, is combated with characteristic energy by Mr. Lawson Tait, who, on their behalf, denies the soft impeachment. It is not merely a question of the personal dignity of these adventurous fœtuses, nor does Mr. Tait hold a brief to assert against all comers their right to even a deformed existence. If such a statement as this is once allowed to obtain credence, the moral scruples which some surgeons feel in treating the fœtal existence as a *quantité négligeable* are apt to be sacrificed to the interests of the mother, these being often apparently opposed to those of her offspring. Hitherto it has been gratuitously assumed that the conflicting interests are irreconcilable, and cases of ectopic gestation which have progressed beyond the sixth month have been allowed to go on until the death of the ill-fated fœtus has encouraged the surgeon to operate in the hope that the danger of placental hemorrhage will have been minimized, if not abolished, by the subsequent devascularization of the placental mass. Apart from the fact that such delay is tantamount to condemning the fœtus unheard, there is reason to believe that the supposed advantages to the mother of the delay are largely and erroneously hypothetical. It seems, in fact, that the interests of mother and child alike are best served by postponing operative interference until the latter has attained a viable age, and then cautiously removing it, and with it, if possible, the placenta. We are pleased to rehabilitate the maligned fœtus and to vindicate its right to "a place in the sunshine," leaving the question of the removal of the placenta to be decided by subsequent experience. It must

not be forgotten that the most fatal complication of operations for the relief of extra-uterine gestation is hemorrhage, septic mischief—which constitutes the most cogent argument against leaving the placenta to come away piecemeal—being vastly less dangerous both in its incidence and its mortality.—*Medical Press.*

Recovery after Swallowing a Teaspoonful of Amyl Nitrite.—Dr. G. E. Shoemaker, of Philadelphia, reports this case in the *Medical News*. He was hastily summoned to see a man, sixty years of age, of robust physique, who had by mistake taken a teaspoonful of undiluted amyl nitrite. About three minutes after the drug was taken the doctor found the man sitting in a chair, with a moderately flushed face, a pulse of 112, and complaining only of a little headache. Being of a sluggish temperament, the patient did not appear to realize the gravity of the situation, and received philosophically the treatment instantly instituted. He was successively given several glasses of warm water; a hypodermatic injection of one-eighth of a grain of apomorphine; mustard in warm water; zinc sulphate in warm water; another one-eighth of a grain of apomorphine; more mustard and warm water; so that just seven minutes after he took the drug copious vomiting of a very hearty unmasticated meal occurred. The evacuated matter emitted a strong odor of amyl nitrite. Vomiting was very copious indeed, the quantity of food, evidently just eaten, being enormous. Digitalis and brandy were now injected beneath the skin; and the patient was put to bed and surrounded by hot bottles. His face was moderately blue; the extremities cold; respiration shallow, but regular; the pulse weak, but only 68 to the minute, five beats being dropped in that time. Strychnine sulphate in doses of one-thirtieth of a grain was frequently repeated; digitalis and brandy were continued, and external heat was maintained. Two hours later the pulse had ceased to intermit, and the patient was even jocular, though weak. The next day nothing abnormal could be detected in his condition. Consciousness was not lost at any time, though the man seemed drowsy and stupid. There were no twitchings or convulsions, no irregularity of respiration. The man was constantly watched and every symptom carefully noted as to time, a record of pulse being taken every five minutes, but no symptoms developed beyond those narrated. To avoid alarming the patient and arousing his suspicions, which seemed to be marvellously few, no effort was made to learn subjective symptoms. Recovery was due to the fact that the patient's absorptive powers were sluggish. He no doubt had a dilated stomach which he had just filled with food. The promptness with which it was possible to empty the stomach and administer stimulants no doubt also helped in the fortunate outcome. An examination of some leading works on therapeutics gives the reader little help as to the proper treatment of poisoning by amyl nitrite. Digitalis and strychnine were pushed in this case because the heart was failing.

Dentition Fever and Its Treatment.—Dr. Müller says that posterity will look with wonder upon the difference of opinion now existing whether there is really a fever depending upon dentition alone. He believes, and bases his belief upon many observations, that certain cases of ephemeral fever occur in children where the most scientific examination fails to show any lesion except eruptive teeth, and the fever rapidly disappears upon lancing the gums. He advises the following manner of performing gum lancing: An assistant fixes the shoulders and legs of the child, while a second fixes the head. The index-finger of the left hand is pushed between the jaws, and the tongue pushed somewhat aside. Then with a scalpel laid flat on the tooth he cuts off the little cap surmounting the point of the tooth (this can be easily discovered by the paler character of the gum in this position), or he makes parallel or cross cuts over the top of the tooth, thus excising a small portion of the gum. If the scarification is done in this manner the point of the tooth will remain free, and a scar will not form over it. The mother is directed to wash the scarified surface several times daily with a soft cloth wet in carbolic acid solution, to prevent infection and prevent the healing of the cut. The amount of blood lost is insignificant. This little operation will always relieve the child when the diagnosis is correct. It is not to be done, however, unless the physician is certain that no other cause for the fever exists.—*University Medical Magazine.*

True and False Angina Pectoris.—Dr. Huchard gives the following table of differential diagnosis between true angina and hysterical pseudo-angina:

True Angina.	*Hysterical Pseudo-Angina.*
Most common between forty and fifty years.	At every age, even six years.
Most common in men. Attacks brought on by exertion.	Most common in women. Attacks spontaneous.
Attacks rarely periodical or nocturnal.	Often periodical and nocturnal.
Not associated with other symptoms.	Associated with nervous symptoms
Vaso-motor form rare. Agonizing pain, and sensation of compression by a vice.	Vaso-motor form common. Pain less severe. Sensation of distention
Pain generally short duration; attitude: silence; immobility.	Pain lasts one or two hours; agitation and activity.
Lesion: Sclerosis of coronary artery.	Neuralgia of nerves.
Prognosis: Grave, often fatal.	Never fatal.

Huchard also discusses the prognosis of angina: Sudden death may occur during the course, or at the end of a painful paroxysm, or, by sudden syncope unattended by pain. Anginal patients are very liable to syncope; the patient falls as if struck by lightning. In other cases death is not so sudden, but rapid, and may be attended with symptoms of asphyxia instead of syncope. In other cases the disease may be terminated by intercurrent affections. The predisposing causes of sudden arrest of the heart in angina are probably lesions of the cardiac ganglia and local ischæmia of the myocardium; the exciting causes are spasmodic contraction or thrombosis of the coronary arteries. The author gives iodide of potash for three or four years in doses of forty-five to sixty grains daily, taking care to suspend it for eight or ten days each month. In rheumatic cases sodium salicylate, rest, even temperature, and dietetic care are always important. The inhalation of nitrite of amyl (this drug relaxes the peripheral arterioles, lowers the blood pressure, and relieves the heart). Nitro-glycerine and hypodermic injection of morphia are also useful for the same purpose, and act much in the same way. Hot applications to the chest, faradization of the cardiac region, with internal administration of diffusible stimulants, belladonna, and small doses of opium have been recommended.—*Hospital Gazette.*

Gastro-Intestinal Exhaustion.—Among the many cases of gastro-intestinal disturbances which occur in warm weather, a certain number may be fairly considered as a class by themselves, due not to poisoning or errors in diet, but best described as cases of gastro-intestinal prostration. The clinical picture is fairly definite. The onset is slow, as a rule; indeed the patient is often unable to give a more accurate date of the beginning of his trouble than "the first of warm weather." There is no history of errors in diet or exposure to cold—as there is no sudden onset of acute symptoms. A general mild anorexia for a day or two, slight irregularity in the action of the bowels, and a little distress after taking of food, have hardly attracted any attention; but the continuance and gradual increase of a mild diarrhœal tendency are the first symptoms heeded. The diarrhœa is unaccompanied by pain, though often attended with flatus. Diet when at all rational has but slight connection with the diarrhœa. The whole picture of the case when carefully noted is quite distinct from that of acute or subacute gastritis, due to irritant ingesta. There is no fever or vomiting, though there may be slight nausea. The chief complaints of the patient are of the annoyance of

the diarrhœa, and of a sense of weakness. The ordinary treatment of a gastro-intestinal catarrh is usually given with a gradual improvement of the patient toward fall. The noticeably good effect of a few cool days on the patient points to the rational explanation of the condition, the greater or less exhaustion of the nervous centres controlling the alimentary tract. The effect of heat upon the human system varies so much in different persons that it is not easy to trace the exact course of its workings. Some people are always "better" in summer; they like hot days, and with such people cases of gastro-intestinal exhaustion are not found. It is the person whose nervous system is below par, or easily exhausted by heat, who is troubled by this atony of all alimentary processes. Indeed, the digestion suffers only as a result of marked nervous exhaustion, affecting chiefly the great ganglionic centres of the sympathetic system. With this theory of the cause of the patient's trouble the indications for treatment are seen to be quite different from those of an enteritis. The diet should, of course, be light and simple, but it should be abundant. The patient should be kept quiet, fed often and regularly, with varied but easily digested foods. Removal from a heated, noisy city to cool localities is of the greatest importance, and care should be taken to avoid overheating or exposure to the sun. The nervous system should be given all the rest possible, as in cases of general nervous exhaustion. Medicinal treatment should be not by cathartics and antiseptics for supposed ptomaïnes, but by thorough administration of nervous tonics and stimulants. —*Boston Medical and Surgical Journal.*

Infection Icterus.—The St. Petersburg correspondent of the *Medical Press* writes that Dr. Hœppener has described a sort of *Infection Icterus* resembling typhoid in its clinical appearance. The phenomena are ushered in with pain in the head and limbs, the temperature gradually rising till it reaches 102° to 103° F., which continues five to eight days. On the fourth or fifth day icterus appears, the spleen is enlarged and the margin of the liver is prominent and painful, the tongue white, and the urine contains albumin from the beginning but becomes dark on the fourth day, although the fæces are normal and sometimes colorless. The course of the disease ranges from between two and three weeks, and usually terminates in recovery. There are two cases, however, on record, where death occurred, the post-mortem revealing great reddening and swelling of the solitary follicles. He had one of fatal ending that lasted four weeks, the fever continuing only five days however, after which followed somnolence, sopor, and death. Urticaria and blood extravasation appeared under the skin. The autopsy showed the usual swelling for solitary follicles, with some of them ulcerated and broken down, infarcts were also present in the kidneys, the liver greatly enlarged, with an intense yellow color, and the gall fluid inspissated.

Strychnine During Pregnancy as an Aid to Labor.—Dr. Duff, at a recent meeting of the Pittsburgh South Side Medical Society, made some remarks in regard to the subject of tardy labor. The discussion prompted him to speak of a remedy he had administered when occasion offered during the past few months. In speaking of it, he stated that his observations had not been sufficiently numerous to justify him in giving a positive opinion. Nevertheless, whether by accident or otherwise, his results, so far in the majority of cases, had been most gratifying. He referred to the administration of strychnine as a remedy preparatory to labor where there is general debility and want of muscular tone; in women who previously have had tardy labors from irregular and feeble uterine contractions and from want of tone in the auxiliary abdominal muscles; in women who have a history of post-partum hemorrhage, and of want of retraction and contraction of the uterus subsequent to delivery; in those who are subject to severe after-pains necessary for the expulsion of clots in the uterus. In all such cases a treatment should be instituted of $\frac{1}{60}$ gr. of strychnine three times a day, beginning from six weeks to two months prior to the anticipated time of delivery, and kept up until a week or ten days before delivery, when, if it is well borne, it may be increased, according to the judgment of the attendant, to $\frac{1}{40}$ gr. or $\frac{1}{30}$ gr., and in some cases to $\frac{1}{16}$ gr. The cases in which he has administered it, for the most part, were those with which he had had experience of tardy labors, post-partum hemorrhage, and severe after-pains. In nearly all of them the improvement over past experiences was so great that the patients themselves were cognizant of it and expressed gratification.—*Therapeutic Gazette.*

Bromoform in Whooping-Cough.—Dr. F. W. Burton-Fanning says that Stepp reported, in 1889, one hundred cases of whooping-cough treated with bromoform without a single failure, and his results were indorsed by other physicians. Dr. Burton-Fanning also reports thirty cases of his own treated with this drug. Bromoform is a colorless, oily liquid with an ethereal odor and sweet taste, insoluble in water. He suspends the bromoform in a mixture, as follows:

Bromoform	℥ j.
Pulv. tragacanth co.	ʒ ss.
Syr. simpl.	ʒ ss.
Aq.	ad ℥ ss.

For children under one year he gives half a minim, up to three years, one minim, up to six years, two minims three times a day to begin with, then, if necessary, these doses may, with safety, be gradually increased until they are doubled. It is important to have a fresh supply once a week, to keep the bottle in the dark, and shake it before taking the contents. Bromoform should never be used when it is of a brown color, as this is due to its decomposition and the liberation of free bromide. He considers bromoform of specific power against the paroxysmal cough, on which the chief dangers of whooping-cough depend. The number of paroxysms with this treatment are much fewer, shorter, and less violent, and the vomiting always ceases, but the duration of the disease is not materially shortened. If the bromoform be discontinued within four weeks, the characteristic cough and attendant miseries return at once. He also finds that this remedy is so specific in its action as to be of great use in diagnosis. In doubtful cases its success or failure to relieve the cough led him to a correct conclusion as to the nature of the disease, as subsequently established by other considerations.—*Boston Medical and Surgical Journal.*

Ichthyol Suppositories in Prostatitis.—Dr. Freudenberg recommends ichthyol suppositories in this affection. He has used them in from thirty to forty cases during the past two years, and only in two did they fail to give relief. The cases were mostly subacute or chronic. Any necessary treatment of the urethra was carried out at the same time. The suppository consists of 0.5 gr., increased up to 0.75 of ichthyol to 2.0 to 2.5 cacoa butter. If any irritative symptoms appeared—and this may happen with any suppositories—smaller quantities of ichthyol were employed. Two, and sometimes three, suppositories were used in the day. The author refers to other cases in which ichthyol has been tried, and more especially to Scharff's forty cases, but here the prostatitis was acute and mostly gonorrhœal in origin, and a ten per cent. solution was injected into the rectum.

Prevention of Cocaine Intoxication.—Dr. Parker (*British Medical Journal*) has discovered that the unpleasant, and even poisonous, symptoms that occasionally follow the local application of strong solutions of cocaine in the nasal and buccal cavities may be entirely prevented by combining the drug with resorcin. This combination has the further advantage of adding the antiseptic, astringent, and hæmostatic properties of the latter drug to the effects of the cocaine.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, October 14, 1893.

THE PHYSICIAN AND HARD TIMES.

THERE has been a very general complaint among physicians as well as the laity that "business" has been poor. The doctor, however, is usually rather shy about complaining, for he gets very little sympathy over his hard times. To the layman this simply means that the community is healthier and consequently happier. The presence of doctors and a police are two signs of a badly ordered government, according to Plato.

We have not heard, however, that dispensary work has fallen off, and it may be that when doctors have hard times it is chiefly due to the fact that their patients when ill do not call for medical service, or if they do, fail to pay their bills.

On the other hand it is quite possible that another factor is at work, and one which will in time become a most important one. We refer to a decrease in sickness on account of the prevention of disease through the observation of the rules of hygiene. For years now the people have been instructed day in and out regarding the best methods of preserving their health, preventing infection, and prolonging their lives. Boards of health have multiplied and are becoming every year more powerful and efficient. Small-pox, which made the fortunes of eighteenth century physicians, is no longer a source of income, nor is typhus, or cholera, or yellow fever. Phthisis now is not kept under care in cities or at homes so much as formerly. The patients who can afford to pay a physician are promptly sent away, as a rule.

With other zymotic diseases the results of sanitation have not been apparently so brilliant. Comparative tables for this city are not strictly accurate, since the classification was changed in 1889. The following, however, may be of some interest. It shows the deaths in this city about twenty and again about ten years ago, as well as at the present time.

	1875.	1884.	1892.
Total deaths	30,709	35,044	44,329
Zymotic diseases	10,968	9,263	9,282
Constitutional	6,090	7,941	7,443
Local	10,760	14,246	21,585
Developmental	1,704	2,244	1,814
Violence	1,187	1,340	2,179
Diphtheria	2,311	1,090	1,436
Scarlet fever	514	608	977
Measles	167	762	864

The death-rate in 1874 was 27.57; in 1884, 25.82; in 1892, 24.26. There has been, therefore, a diminution in the death-rate of about five per thousand. This probably represents an equal proportionate diminution in the sick-rate. The zymotic diseases seem, on the whole, to be less in number, although the year 1874 represented an epidemic of diphtheria, to which we may be again liable. Furthermore, the best results of preventive medicine are found in the well-to-do, the more intelligent, and better-housed classes; in other words, those that can pay the physician.

We believe it may be safely said, then, that there is at least less severe sickness than formerly, and that this is one element in the hard times of which physicians speak —we will not say complain.

The physician, to his credit, has always been foremost in his advocacy of preventive medicine. He will not any the less cease his advocacy because it pecuniarily does him harm. Happily, the medical man is not guided by mercenary impulses alone. He recognizes that there are many things which he must do simply because they are right.

OSTEO-ARTHRITIS.

RHEUMATIC gout, known also as rheumatoid arthritis, rheumatic arthritis, asthenic gout, and best of all as osteo-arthritis, is a chronic constitutional disease of lowered vitality, occurring most frequently in persons under forty who give a family history of gout, rheumatism, phthisis, and sometimes nervous disease. Its assumed causes are many, such as long-continued hard work, mental worry, occupations favoring exposure, cold, dampness, injury, the wretchedness of poverty, and a trophic neurosis of undetermined origin. An attack of acute rheumatism starts it up occasionally. It may appear for the first time at any period of life, in old age and during infancy. The earlier it begins, the more unfavorable the outlook. It is one of the earliest degenerative conditions; and throughout its course the changes are partly degenerative and partly inflammatory. The power for good that lies in early diagnosis is impossible to over-estimate, since the efficacy of treatment depends largely upon the removal of all depressing causes, and upon the improvement of the general nutrition.

Before there is any joint trouble, there is usually anæmia more or less marked, transient sharp pains in the joints and muscles, especially on the inner side of the wrist or the ball of the thumb, numbness and tingling in the extremities, a crackling sensation and some stiffness in the joints on movement, the whole often accompanied, especially in the young, by rapid pulse and high tension, headaches, pigmentation, and stiffness of the neck and of the jaw on waking. The pain in the thumb, the inner side of the wrist, in the neck and jaw are particularly significant. It is said that osteo-arthritis is the only arthritic disease that attacks the temporo-maxillary articulation. Pain and stiffness here, and tenderness over the spines of the vertebræ, are sometimes the earliest premonitory signs.

Osteo-arthritis is not rheumatism, neither is it gout; rather is it an offshoot from a parent stem of which gout and rheumatism are both branches. Gout is chiefly confined to the male sex. Rheumatism affects men and

women equally. Osteo-arthritis attacks the weak and slender, and women far more frequently than men. There is little or no fever, dyspeptic symptoms are not prominent, and the heart and its membranes are not involved. Attacks are frequent, increasing in severity with each occurrence, symptoms are obstinate, the small joints are affected in preference to the large ones, and several may be implicated simultaneously. Rheumatic gout lasts ten, twenty, thirty years, is slowly progressive, and involves joint after joint. It does not directly cause death, though it adds materially to the burden of living. The disease runs a slow, definite course that is but slightly modified by any remedies yet known. Unless carried off by intercurrent disease, the death of the osteo-arthritic is due either to phthisis, nephritic troubles, infection from bed-sores, or cerebral hemorrhage. Affections of the lungs and kidneys are the commonest causes of death, though exhaustion induced by pain is also a factor in bringing life to a close.

One of the valuable books of the year is "A Dissertation on Osteo-Arthritis," by W. H. Russell Forsbrook. It contains six chapters: on the history of the disease, on etiology, morbid anatomy, pathology, clinical history, treatment, and illustrative cases. There is a careful *résumé* of all the old views, and evidence of much painstaking research to establish some that are new. Quoting Duckworth: "The nervous system is markedly implicated in the arthritic diathesis, and both rheumatic and gouty diseases point to the probability of there being a trophic centre or centres for joints situated in the spinal marrow. Morbid and unstable conditions of these may result in a definite neurosis, which itself may be either inherited, acquired, or modified in particular instances," the author conjectures that the deficiency of oxygen in the blood of persons predisposed to osteo-arthritis may over-excite the vaso-motor centre in the medulla and cause constriction almost to obliteration of the minute vessels supplying the smaller joints, and, it may be added, the small peripheral nerves also, in this way cutting off their blood-supply and consequently interfering with their nourishment. Likewise the blood-supply through the vessels of the nerves going to the joints, etc., will be more or less interfered with, thus giving rise to degeneration of some of their fibres and so becoming another factor in the malnutrition of joints. On account of this deprivation of blood, these joints would ultimately undergo an organic change, though at first subject to a mere functional disturbance. After a time the stimulation of the vaso-motor centre must end in its exhaustion, giving rise to dilatation of the vessels and changes in the joints, and perhaps in the peripheral nerves also. These two forces repeated over and over again, would explain, according to the degenerative and inflammatory theory, the morbid features present in the joints in osteo-arthritis, and also the changes in the shafts of the bones themselves, for their nutrition would be interfered with through their dependent nutrient vessels. In this affection is found the one great exception of securing rest to a diseased joint. Except in an acute attack, active and passive movements of the joints must be kept up as long and freely as possible. Muscular strain that is relatively great should always be avoided, as lifting, carrying, climbing, or occupations making great demands upon the small joints. Such activities may induce an acute attack. The soil is always favorable in the predisposed, and strain, either mental or physical, precipitates the difficulty.

The treatment of rheumatic gout, or osteo-arthritis, consists in the removal, as far as possible, of all depressing influences, in the improvement of the general nutrition, in the administration of drugs and the employment of measures that will produce absorption. In no condition is environment, and all that it implies, of more importance and of greater force. It is one of the cases where experience proves that surrounding relatively perfect for the patient will overcome or hold in abeyance the effects of heredity that make for disablement and restricted usefulness. A warm, equable, dry climate is the ideal. Sunshine, daylight, fresh air, and bright cheerful rooms, outdoor exercise and regulated gymnastics, the correct uses of water, and proper clothing are among the essentials. The patient must always be well nourished, meat forming the chief article of diet. Whatever food is found to improve the general health may always be given with advantage. The disease arises from so many different causes that there can be no fixed rules of medication. If anæmia is present, the blood must first be restored to its normal condition and there maintained, which is best done by the cold affusion, the needle-bath, and the Scottish douche. Acute attacks are best treated by light diet, absolute rest in bed, heat to the affected parts; small doses of mercury first, and whatever remedy afterward that the patient's prominent symptoms or general condition seem to call for. Prostration is out of all proportion to the severity of the attack, apparently, and in many instances requires special and continued attention. Each case is peculiar, and must be treated on its own merits.

In the chronic form of osteo-arthritis the drugs most serviceable are iodides, free iodine, arsenic, guaiacum, actæa racemosa and fraxinus excelsior; and quinine, strychnine, and nux-vomica. Cod-liver oil for a long time in fairly large doses is the most valuable remedy of all. When the joints are painful or swollen, they may be painted with the tincture of iodine, strapped with plaster, or rubbed with belladonna liniment. Garrod speaks highly of the use of a liniment of cantharides that is more convenient than an ordinary blister; he also recommends rubbing the joints with iodide of cadmium night and morning. Burying the affected parts in sand as hot as it can be borne for an hour or two, three times a day, is advised by Trousseau. Electricity (continuous current) relieves pain, lessens deformity, aids absorption of nodosities, and restores wasted muscles to their normal bulk and tone. The intensity of the current should be about fifteen to twenty milliampères. The applications, from ten to fifteen minutes in duration, should be made every day for the first month. Mild Turkish baths are of benefit. Mineral springs and baths that are highly recommended are Royat, Schwalbach, Pyrmont Spa, and Aix les-Bains. Above all and beyond everything, management is the chief factor in treatment. To take an illustration from the industrial world, the patient is the laborer, nature is the capital, and the physician is the manager, the middle man, who directs the forces of each into channels that result in the relatively perfect health that is a fortune.

There are Fifteen Vacancies in the Medical Department of the U. S. Army.

FALSEHOOD AND CRIMINAL WOMEN.

In certain localities, women, like the traditional Irishman, have the reputation of thinking too much of the truth to be trotting it out on all occasions. For Lombroso and his disciple Ferrero (*Archives d'Anthropologie crim., de Criminologic*, March, 1893), lying is almost a natural attribute of womankind, even if upright and virtuous. But strangely enough, these writers fail to define the virtuous woman. An ancient chronicle states that the virtuous woman opens her mouth with wisdom. And this same authority affirms that wisdom is first pure, then peaceable, gentle, and easy to be entreated, full of mercy and good fruits, and without hypocrisy. The Lombroso school preaches the inglorious doctrine of irresponsibility. We do what we do because we are what we are; and we are what we are because our ancestors were what they were. As volition counts for nothing, since conduct is purely automatic, posterity and others are kindly exhorted to grin and submit gracefully to adverse automatic acts that are as they are because things were as they were. Many mistakes based upon this theory of fatal determinism have been mercilessly exposed by Baccaro at the Congress of Criminal Anthropologists in Brussels. Yet Lombroso deserves credit for the great service done by his practical object lesson, that to combat crime it is necessary to study the criminal.

That lying is the natural attribute of womankind, Ferrero thinks is due to weakness, to insufficiency, to modesty, and to various social conditions that will disappear in some improved state of society. Criminal women deny offences in spite of proof positive. The mental attitude that prompts such a woful exhibition seems to be a state of intellectual insensibility that results in a total absence of logic. By repetition these startling accounts take on a semblance of reality in the mind of the narrator (anto-suggestion). As Ferrero points out, the study of womankind is the study of contradictions. Side by side with this propensity for falsehood is another equally fateful, and that is a powerful impulse toward undue veracity. Guilt is avowed unblushing and without constraint. This, too, is a psychic phenomenon that has its origin in emotion. Needless truth and unnecessary lies impose on juries, Ferrero thinks, and result too often in the acquittal of women that are dangerous to the community. The fact is, Charles Lamb summed up the ideal of truthfulness when he said that truth is too precious to be told to everybody. The ideal woman is truthful, but without being too truthful, reticent, without being too reticent, and many other things, without many other things.

THE EYE-SYMPTOMS OF BRAIN DISEASE.

Considering the eye from the point of view of development, the retina and optic nerve are to be regarded as a prolongation of the brain. The three sheaths of the optic nerve are a direct continuation of the three meninges, dura mater, arachnoid, and pia mater, separated by the subdural and subarachnoid spaces, which communicate with the same cerebral spaces. These spaces are lined with endothelium and are to be considered as lymph-channels of the eye. Schwalbe, Quincke, Deutschmann, and Gifford have demonstrated that in these spaces there is a lymph-current from the brain to the eye.

This subject of eye-symptoms is treated at length in a paper by Dr. Charles Zimmermann, in the *Medical and Surgical Reporter*, July 29, 1893. One of the most important and most interesting ophthalmoscopic symptoms is the optic neuritis usually called choked disk or papillitis. The optic disk presents the aspect of congestion, with œdema, increased redness, blurred edges, radiating striation of whitish nerve-fibres spreading into the retina, and sometimes small hemorrhages with general cloudiness. The arteries are concealed at their emergence and narrowed; the veins are dilated, tortuous, and look dark as if cut in pieces. The trunk of the optic nerve shows changes of an inflammatory character. In case of a rapid course, as in syphilis, the development of papillitis may take place in two or three weeks, remain at its height for two weeks, and then subside. But when caused by a cerebral tumor, optic neuritis progresses very slowly. Then it may last for weeks and months, and subside and pass into atrophy. Papillitic atrophy is brought about by the shrinking and strangulating influence of the connective tissue into which the newly-formed inflammatory products have been transformed. A strange peculiarity in cases of much marked pathological change, is the integrity of sight, visual field, and color perception. A sudden blindness in optic neuritis comes on only when associated with mischief farther back in the optic path. The amblyopia caused by the inflammatory process when at its height, may nearly disappear as the inflammation subsides, but again be renewed by the subsequent contraction of the connective tissue. Even after the healing of the papillitis with restoration of vision, sight may be lost entirely from some affection of the optic fibres within the cranium and without further ophthalmoscopic changes. Intra-cranial diseases are the most common causes—as tumor, meningitis, abscess, hydatid disease, and cerebral softening. Neuritis occurs in about four-fifths of the cases of tumor; and glioma, sarcoma, tubercle, and syphiloma are usually associated with optic neuritis. Experiment and observation make it seem probable that the papillitis dependent upon intra-disease originates in a descending inflammation of the optic nerve, an inflammation conveyed from diseased portions of the brain into the subvaginal spaces by a powerful lymph-current. The pathogenetic material will accumulate chiefly at the culde-sac of the space next to the globe, and therefore produce the most striking changes at the intra-ocular end. Direct pressure on the optic fibres in the chiasm, at the optic foramen, or at the base of the brain, by tumors, internal hydrocephalus, distended third ventricle, meningeal exudations, aneurisms, or exostoses of the cranial bones, may cause simple atrophy of the optic nerves. Blindness, however, may occur in cerebral disease without ophthalmoscopic change.

Morphinomania among Medical Men.—Some statistics as to the prevalence of morphinomania in France, recently published by M. Lacassagne, show that the destructive habit finds a large proportion of its victims among members of the medical profession. Of 545 morphinomaniacs as to whom he was able to procure information, 289 were doctors. It is well known that several of the most distinguished men of the profession in Germany who have died in recent years were devotees of the fatal drug.

News of the Week.

The Medical Society of the County of St. Lawrence, N. Y.—The Medical Society of the County of St. Lawrence will hold its semi-annual meeting at the City Hall, Ogdensburg, Tuesday, October 17, 1893, at twelve o'clock.

Antisepticism and Edinburgh Surgery.—A correspondent sends *The Lancet* the following: "'For clean, aseptic surgery go to Hamburg or Glasgow; for dirty surgery go to Edinburgh.' This short and pithy advice, the dictum of a famous Glasgow surgeon, was given to a circle of medical men on the deck of a Leith and Hamburg steamer in the summer of 1890, when the whole medical world seemed to be doing the pilgrimage to Berlin. As the group was composed almost entirely of Edinburgh men, the above remarks were greeted with a shout of laughter; nevertheless, there may be something in the statement to which Edinburgh surgeons may well give heed, particularly as the recent American testimony (that of the 'intelligent foreigner,' which is supposed to foreshadow the deliberate conclusion of posterity) points in the same direction."

Napoleon the First's Medical Advisers.—From a curious work by M. Maze-Sencier, entitled "Les Fournisseurs de Napoléon Ier," we glean a few details concerning the *petit caporal's* physicians, surgeons, chemists, dentists, corn-cutters, etc., who cost him annually the sum of 201,700 francs. His chief physician (Corvisart) received 30,000 francs, *plus* 4,500 francs for office expenses; Hallé, his physician-in-ordinary, received 15,000 francs; Lanfrancque, Guillouneau, Lerminier, and Bayse, who took duty in turns at the Infirmerie Impériale, were each paid 8,000 francs; four other practitioners, who acted as consulting physicians (Malet, La Pieux, Pinel, and Aubry), received each a salary of 3,000 francs; the chief surgeon (Boyer) was paid 15,000 francs, and the surgeon-in-ordinary (Yvan) 12,000 francs. It was Yvan who dressed Napoleon's wound at Ratisbon in the year 1809, and his portrait appears in Gautherot's picture—now at Versailles—of the incident. The four surgeons of the Imperial Infirmary were Horeau, Vareillage, Lacouenère, and Ribes, and the pay attached to their office was 6,000 francs. Napoleon's surgeon at Saint-Cloud, which he frequently inhabited, was Lassoujade, who received 4,500 francs. Each of his consulting surgeons received 3,000 francs; they were Pelletan, Percy, Sabatier, and Dubois. It was Dubois who was in attendance on the Empress, Marie-Louise, in her confinement. The process being long and laborious, he communicated his anxiety on the subject to the Emperor, whose reply was, "Faites comme si vous aviez affaire à une bourgeoise de la rue Saint-Denis; surtout, Dubois, sauvez la mère." The case did well, and the Emperor, delighted, told Corvisart to ask Dubois what reward he desired for his services. The latter, who was evidently a man of a practical turn of mind, gave the following modest reply: "Dis à l'empereur que je désire beaucoup d'honneurs et beaucoup d'argent." Let us hope that a *douceur* of 100,000 francs and his elevation to the rank of baron satisfied the cravings of the ambitious accoucheur for advancement. Napoleon had also his surgeon-dentist and his *chirurgien-pédicure*, whose salaries were respectively 6,000 francs and 2,400 francs. Seven *pharmaciens*—one being at St. Cloud—received an aggregate sum of 23,000 francs per annum. The Emperor professed a disbelief in medicine, and frequent discussions on the subject took place between him and Corvisart, who, true to his courtier instincts, always allowed himself to be convinced by his Imperial master's arguments. Corvisart, however, had his revenge when he cured him of scabies caught at the siege of Toulon. The playful sarcoptes is evidently no respecter of persons.

The Illinois State Board of Health, at its last meeting, decided to resume the publication of the reports on medical education. For the last two years, owing to various causes, none have been printed. Dr. J. Collins Warren, President of the Section of Pedagogy of the Pan-American Medical Congress, in his address, after reviewing the subject in this country, says: "The reports on medical education by the Illinois Board, I do not hesitate to say, have exerted a more powerful influence on the movement in education than any other publication which our medical literature has produced." This is undoubtedly true. These reports were object-lessons to the profession and to the schools, and presented truthfully the status of the colleges. Dr. F. W. Reilly is now engaged in preparing the forthcoming report. He is eminently qualified for the task, having assisted in the preparation of nearly all the reports that were issued by the Board.

To Medical Students.—Our medical colleges are now being filled with ambitious and eager young men. Many of them have doubtless received words of advice from parents, instructors, and friends. All, however, may well bear in mind the words of Sir Astley Cooper, spoken many years ago at the Royal College of Surgeons: "Gentlemen, you are about to enter on a noble and difficult profession; your success in it depends on three things: First, on a good and thorough knowledge of your profession; second, on an industrious discharge of its duties; and third, on the preservation of your moral character. Without the first—knowledge—no one can wish you to succeed; without the second—industry—you cannot succeed; and without the third, even if you do succeed, success can bring you no happiness."

The Death of Dr. William F. Hutchinson, of Providence, one of the most prominent surgeons of Rhode Island, is reported as having taken place on Monday, the 2d inst.

The New York Infant Asylum.—Dr. Egbert H. Grandin writes as follows to the *New York Medical Journal:* The resignations from the Medical Board of the New York Infant Asylum and recent comments in one of the New York daily papers lead me to send you the resolutions adopted at the last meeting of the defunct board, authority to publish which was given me at my discretion. I have hitherto refrained from doing so for the reason that I did not see any good to be gained by washing what doubtless the Board of Managers will term "dirty linen" in public. In view, however, of the reported comments of certain of these managers, it seems eminently fitting that medical men should understand distinctly the causes which led to wholesale resignations

from one of the greatest charities (using the term in its true sense) in the city, for thereby alone will medical men be enabled to judge as to whether their self-respect as men and as physicians will allow them to fill the vacant places under the present management. Medical men may be cheap, as it has been stated, but when a principle is at stake medical men ought to stand together and thereby furnish a living denial of the allegation. All positions are not golden ones, and official titles at the cost of one's self-respect are unworthy of our acceptance. I append the resolutions:

Whereas, The Medical Board of the New York Infant Asylum respectfully requested the Board of Managers: 1. No faithful medical officer shall be removed without cause. 2. Nominations to fill vacancies shall emanate from the Medical Board;

Whereas, These reasonable and just demands have been peremptorily refused by the Board of Managers;

Resolved, That, in dignified protest and in justice to themselves as men and physicians, the following members of the Medical Board hereby resign.

These resolutions were signed by eighteen medical men who for years had given their time, their skill, and their money to the institution. These resolutions were adopted after nearly six months' fruitless endeavor to adjust matters amicably and equitably. This action is now characterized as "tomfoolery." One of the managers is reported to have said that he did not care a "picayune." The medical profession may now judge for itself. The gentlemen who resigned have absolutely no nuts to crack. They left the institution they had served well with regret and they wish well to those who succeed them.

Harvard Medical School.—The Harvard Medical School has an entering class this year of somewhat over ninety—a falling off of about twenty from the number last year.

More Board of Health Physicians.—At a meeting of the Board of Estimate and Apportionment, held September 28th, an appropriation of $3,000 was made to the Board of Health for the employment of fifteen extra physicians for the free vaccinating corps. At the same meeting $539,248 was voted for public-school improvements, and $50,000 for the further purification of the Croton water-shed.

Hereditary Polydactylia.—Charles Hodge, a lad, thirteen years of age, of Newark, N. J., who was born with twelve fingers and fourteen toes, was recently relieved of the extra members at St. Barnabas' Hospital. It is stated that this superfluity of fingers and toes is a hereditary characteristic on the maternal side, running back for several generations, and that among the family relics is a bottle of alcohol in which are preserved a number of fingers and toes removed from various ancestors.

The Death of Dr. Clarence Glisan, of Portland, Ore.—Clarence Glisan, A.B., M.D., died in Portland, Ore., August 30, 1893. About a week previous to the time of his death he was attacked with appendicitis, which grew worse, and resulted in an operation for the relief of his suffering. The operation revealed a perforated ulceration of the bowel near the appendix and serious disease of the appendix itself. Death soon followed the operation, the result of general peritonitis and exhaustion. Dr. Glisan was twenty-eight years of age, born in Portland, and was the son of the late Dr. Rodney Glisan, one of Portland's oldest and most celebrated practitioners. Young Dr. Glisan graduated with honor in the literary department of Yale University, receiving the degree of A.B. He graduated at the College of Physicians and Surgeons of New York in 1890, and took a further course at Bellevue Hospital, where he served as house surgeon, and graduated in 1892. He then opened an office and began practice in Portland. He was a conscientious student and in love with his profession, and those who knew him looked forward with pleasure to the time when he should stand upon the very foremost plane of professional life. "His death is untimely and his brethren mourn." He leaves a mother and two sisters, besides his younger brother, Rodney Glisan, Esq., a rising attorney of this city.

Dr. Jesse Lee Morrill, Secretary of the Obstetrical Society, is reported to be seriously ill of septicæmia contracted at an autopsy.

Cholera is Abating in Russia, and the general outlook is good accordingly.

Ohio State Association of Railway Surgeons.—The second annual meeting of the Ohio State Association of Railway Surgeons was held in the Forest City Hotel, Cleveland, October 12 and 13, 1893.

The Cincinnati Academy of Medicine.—The opening sessions of this society give promise of a fruitful year's work. Instead of a committee laboring with members to get them to read papers and to take part in discussions, members are clamorous for assignments when they may have an opportunity to read or speak. This is as it should be, and calls out large audiences. Lancet Hall is already too small to accommodate the numbers in attendance, and the necessity for a home building is apparent. The building fund grows slowly, but will fatten greatly during the coming year.—*Cincinnati Lancet and Clinic.*

Insomnia Parties.—A society young woman of Buffalo has devised a novel entertainment, which is shortly to be made public. It is to be a "reception for people who can't sleep at night." Among her friends, she says, are a great many very delightful people who are troubled with insomnia, and who confess that they spend many frightful, wakeful hours walking the floor, looking out of the window, rocking in easy-chairs, trying to read or write, and in other useless and tiresome occupations. When her plans are fully matured this original young woman intends, on at least two nights in every week, to be "at home" to those distressed female friends from midnight until morning. The guests are requested to appear in any unique, respectable bedroom gown, bath robes not excluded; the lights are to be dim, soothing music and stupid conversation will be the only diversions permitted, hot chocolate and light wafers will be served, couches and easy-chairs will be provided in abundance, and the insomnia victims are earnestly desired to fall asleep as soon as possible. It is whispered that prizes will be offered for the first snore, but this detail is not authentically announced. The reception is to be a fact, however, and an eager expectancy as to invitations is in the air.

Society Reports.

Pan-American Medical Congress.

First Meeting, Held at Washington, D. C., September 5, 6, 7, and 8, 1893.

(Special Report to the MEDICAL RECORD.)

(Continued from p. 475.)

SECTION ON HYGIENE, CLIMATOLOGY, AND DEMOGRAPHY.

ALBERT L. GIHON, M.D., MEDICAL DIRECTOR, U. S. N., WASHINGTON, PRESIDENT, IN THE CHAIR; ENGLISH SECRETARY, PETER H. BRYCE, M.D., TORONTO, CANADA; SPANISH SECRETARY, PEDRO JOSÉ SALICRUP, M.D., NEW YORK CITY.

THIRD DAY, THURSDAY, SEPTEMBER 7TH—MORNING SESSION.

Sanitary Precautions.—DR. J. E. MONJARAS, of San Luis Potosi, Mexico, read a paper in Spanish on "Sanitary Precautions, Isolation, and Disinfection, etc." He took emphatic ground for the control of all contagious and infectious diseases. They should be isolated in suitable buildings or tents. Rooms vacated by such patients should be scientifically disinfected, as well as all clothing, furniture, etc.—in fact any substance or material that might retain or convey the disease. He discussed modern disinfectants and their scientific application.

It is clearly the duty of medical men to instruct families in sanitary matters as well as on all points of public health. He knew that the task was a very difficult one, but it must be done in the interests of mankind.

Personally, he favored a general hospital to receive all patients suffering from any disease from which others might become infected. An International Congress should deal with the matter and devise measures. It was vastly important to mankind. Hospitals and tents he deemed best for purposes of isolation.

Next in order he considered the increased safety to the general public as a result of such isolation and precautionary measures in the curtailing and stamping out of disease.

Disease-germs and their dangers were dwelt upon. The dangers of such germs in dust scattered by wind. The mouth is merely a door of entrance to the body, an excellent culture medium.

Referring to infected clothing, he spoke of the safest of methods, or the English, that of destroying it by fire. He illustrated the danger of infected clothing, citing a case where a ball-dress conveyed disease—typhoid fever. It had been left in a room where a child had had typhoid.

Germs and spores. He referred to spores as being almost indestructible. Dr. Monjaras closed a lengthy paper, embodying the latest views of sanitarians.

Practical Measures in the Prevention of Tuberculosis, was the title of a paper by DR. LAWRENCE FLICK, of Philadelphia. The history of tuberculosis, he said, was a broad demonstration of its communicability. He then entered on a very full and comprehensive statement of facts regarding this dread disease, one so fatal to the human family. The excellent work done in Philadelphia by its Board of Health, in tracing cases of tuberculosis to infected houses, was fully explained. Death after death had occurred in the same dwellings—in short, infected premises. He made the remedy plain.

Spain and Italy by precautionary measures had greatly lessened the mortality. Similar measures introduced in England had reduced the mortality fifty per cent.

Tuberculosis in men and animals, and its general distribution, followed. The paper was a masterly summary of the latest evidence bearing on tuberculosis as a communicable disease. The paper met with warm approval.

In the absence of their authors a number of papers were read by their titles in English and Spanish.

International Uniformity in Quarantine.—DR. JUAN J. ULLOA, of San José, de Costa Rica, Central America, read his paper in English on "International Uniformity in Quarantine Regulations." He introduced the subject by stating that medical men were the apostles of health. To do effective work, the people of the American continent must be educated up to the standard of scientific requirements.

In Spanish America the sanitary regulations of ports, as far as their marine hygiene was concerned, were very defective. They, as a whole, lacked a proper quarantine service, and were wholly wanting in modern disinfecting apparatus.

He spoke of Costa Rica as having no established quarantine service worthy of the name. The Spanish American Republics, he said, failed to protect themselves, and consequently, if infected, endangered all countries with whom they had commercial relations. He deemed the lack of a proper system responsible for the readiness with which Spanish America declared a quarantine against any infected port or country; as once invaded by any contagious or infectious diseases, the Spanish American Republics were almost powerless.

He proposed a broad-gauge system to meet the want—"A Pan-American system of hygiene and quarantine." A code should be formulated for all the countries being constituent members of the Pan-American Medical Congress; such countries should have a National Board of Health, under central control, the whole being subject to instruction, on all matters of public health, to the International Board of Health. As head-quarters for the latter, he suggested Washington as the centre. The International Board to deal with all matters for the welfare of the American continent. The scheme outlined by him was an extensive one, and if adopted, will be of great value. The paper was timely, and carefully elaborated. His having read it in English was a delicate compliment to the Section, and was fully appreciated.

An interesting discussion followed, Surgeon-General Muniz, of the Peruvian Army, and Dr. Peter Keyser, of Philadelphia, taking an active part. It covered the whole question of Maritime Sanitation. A committee was named, when the views of Drs. Muniz and Keyser, being those of the Section, were embodied in a motion and carried.

DR. PALTON, of New Orleans, La., took up the subject of yellow fever, and the duties of shipmasters at sea, when it appears among their crews. Many sailors died on shipboard for want of the most ordinary precautions. Governments should protect shipping interests wherever trading with the Southern Hemisphere. A motion embodying Dr. Palton's views was carried.

The Distribution of Diseases.—DR. WOLFRED NELSON, of New York City, formerly of the State Board of Health, Panama, South America, read a paper entitled "The Distribution of Disease, or Isthmian Practices, or the Direct Responsibility of Colombia, South America, in the Burial and Unburial of the Dead on the Isthmus of Panama." The paper dealt with an old-time practice, one still in vogue on the American Isthmus, or that of burying and unburying the dead. A custom due to using the same grave over and over again. The dangers of liberating millions upon millions of germs of smallpox and yellow fever, as well as other infectious and contagious diseases, received vigorous treatment.

The Isthmus of Panama was described as being the "Gate to the Pacific." The distribution of yellow fever, up the coast of Central America and Mexico, and down that of South America, was clearly shown all by way of Panama.

Despite a vigorous protest made some years ago on the Isthmus, the practice of digging a small cemetery over and over again goes on, to the profit of its *concessionnaire* and the endangering of many.

The Boroedas system was explained. A species of stone quadrangle filled with niches or openings large enough for a single coffin. It was denounced as dangerous to a

degree; a mass of masonry infiltrated with products of disease.

From time immemorial the Isthmus of Panama has been historic as a pestilential and death-dealing spot, or a disease-producing and distributing centre. While Isthmian practices continue it will remain so. He said, "In conclusion, I can but add, in the words of a distinguished American, a statesman admired at home and respected abroad—what obtains there, 'is a condition and not a theory.' It now remains for this body of sanitarians and experts to say what shall be done with it."

Is Leprosy Contagious?—Dr. Lee, of Philadelphia, followed with a paper on "Leprosy." He reported some five hundred or six hundred cases in the United States. He had collected the data largely from dermatologists and others. He was inclined to think that the exact number of cases was less than five hundred or six hundred, as probably some of the cases had been seen twice. He deemed it a very dangerous disease and one calling for legislation. He said that, as an outcome of efforts made in Pennsylvania, some legislation had been enacted to keep out the loathsome disease, that all lepers should be returned to the country whence they came.

It should be met (the disease) by a maritime quarantine of exclusion. He believed in the absolute segregation of lepers. Of the cases reported by him, 117 were known to the authorities; of 90 cases, 7 were in hospital and 3 under treatment. His data he said were imperfect; 10 were Americans, 6 Chinese, 12 South Americans, etc. He referred to the famous Philadelphia case that made such a stir some time ago—that of a cook in a hotel.

Following Dr. Lee's paper, the Section adjourned to 3 P.M.

Afternoon Session.

Dr. Beaven Rake, Medical Superintendent of the Trinidad Leper Asylum, and lately a member of the Leprosy Commission to India, read a paper in which he discussed the possibility of leprosy being communicated from lepers to healthy people.

The Chairman tendered the thanks of the Section to Dr. Rake for his valuable communication, based on ten years devoted to the study of leprosy in Trinidad and India.

Tuberculosis and Leprosy.—The rest of the afternoon was devoted to a discussion on tuberculosis and leprosy. Dr. Peter D. Keyser, of the Philadelphia Board of Health, opened the discussion on tuberculosis. He said we must educate the public. The Philadelphia Board of Health, like all others, had had its troubles. A law should be made that the public will respect; when they know that it is for their benefit and sustained by authority, they will accept, but not before.

Dr. A. N. Bell, of Brooklyn, said that all were familiar with the scientific efforts to curtail the disease. He deemed a thorough system of registering deaths necessary, such as obtains in England. He was opposed to having consumptives massed in hospitals. He was fully convinced that the disease was infectious. All were familiar with the stifling bedrooms of consumptives, be they of high or low degree. A lengthy debate followed, all being in harmony as to the dangers of the disease. The whole question concerns the people, and should be made an object-lesson for them.

Dr. Peter H. Price, of Toronto, Deputy Registrar-General of Ontario, had examined the death statistics of three counties in that Province, taking all returns for eleven years back. He had data of 1,184 deaths from tuberculosis, in three counties averaging from 3,000 to 4,000 each. He noted that in 813 of the cases thirty-three per cent. of the names were repeated in the lists.

Action should be taken to prevent its dissemination. The name tuberculosis should be added to the list of contagious diseases, with a view of preventing its spread. There should be State as well as general control of railways and steamers, thereby preventing consumptives travelling in cars or steamers, on which they undoubtedly leave contagion and thereby infect others. Dr. Bryce's views were in harmony with those of Dr. Gihon, whose opening address covered the subject of the dangers left in the train of all phthisics.

As a direct outcome of Dr. Lawrence Flick's able paper and the discussion, the following motion by Dr. Peter H. Bryce, seconded by Dr. Flick, was carried.

Resolved, That it is the view of the Section of Hygiene, Climatology, and Demography, that in view of the fact that tuberculosis causes more deaths than any other disease, that it is now known to be communicable, especially to persons living in houses and shops with consumptives, that the attention of National, State, and Municipal authorities be directed to the necessity for controlling the dissemination of the disease: 1. By notification by physicians and landholders. 2. By the registration of the residences of the tubercularized. 3. By controlling their movements so far as possible. 4. By the establishment of hospitals and homes for the infected poor.

The discussion on leprosy was opened by Dr. Lee, of Philadelphia, the reader of the paper on leprosy, at the morning session. Practically he restated his case as to the great dangers to the public from lepers, and was in favor of legislative interference, etc.

He was followed by Dr. Wolfred Nelson, of New York City, for many years a practitioner in the tropics, and who had given the disease special study in its own habitats. Dr. Nelson emphatically denied that lepers were dangerous to the public. From statements based on experience he marshalled an array of facts in proof of his views—they being in perfect harmony with Dr. Beaven Rake's extended experience. He spoke of domestic or American cases, citing the Galveston case, where a married man had had the disease twenty years, yet his wife was perfectly healthy. During the whole time they had lived together as man and wife. In this vast republic the few cases cited by Dr. Lee were of no moment. In Canada the disease in the maritime provinces was dying out. Of children born to lepers in the Hawaiian Islands only twenty per cent. became lepers. He warmly appealed to a sense of fairness and justice, and begged the Section to do nothing rashly to add to the burdens of an afflicted class. "The truth, the whole truth, and nothing but the truth," he said. Why legislate against a harmless class when syphilitics and consumptives, known and accepted sources of positive danger, go free? He apologized for referring to his own work on leprosy, as published in the reports of the California State Board of Health some years ago. He referred to the Trinidad Leper Asylum, presided over by Dr. Rake, an institution well known to the speaker, who there had made photographs of many of the patients. He closed his appeal for fair play, based on facts, not theories, by stating that for eight and twenty years the Sisters of Charity had had charge of the Leper Asylum at Trinidad. During that long interval, surrounded by and attending exclusively to lepers, not a single case had developed among them. He asked the meeting wherein laid the so-called dreadful contagion of leprosy?

When the motion was put the large meeting sustained the views of Dr. Nelson. Drs. Lee and Shakespeare, of Philadelphia, dissenting. On motion of Dr. Baker, of the Illinois Board of Health, Dr. Lee's motion for legislative interference was tabled.

The meeting then adjourned to the following day.

Boric or Boracic Acid, though used so much as an antiseptic, is in reality a very inefficient substance. The minimum degree of concentration at which it is at all reliable is 1 to 13. This means over one ounce to the pint, a strength very rarely used in practice.

In Eczema situated at the junction of mucous membrane and skin, a simultaneous treatment of the mucous catarrh is absolutely necessary.—Jamieson.

CANADIAN MEDICAL ASSOCIATION.

Twenty-sixth Annual Meeting, held at London, Ontario, September 20 and 21, 1893.

(Reported by our Canadian Correspondent.)

FIRST DAY, WEDNESDAY, SEPTEMBER 20TH.

THE meeting was called to order by the retiring President, DR. J. L. BRAY, of Chatham, who after a few preliminary remarks introduced DR. CHARLES SHEARD, of Toronto, the President elect.

The President's Address.—DR. SHEARD expressed his grateful appreciation of the high honor which had been conferred upon him. When he looked upon those who in the past twenty-five years had preceded him in office, and saw such names as Sir Charles Tupper, Sir James Grant, Dr. Howard, Dr. Osler, Dr. Hingston, Dr. Mullen, and many others, who might be said, as the pioneers of medical practice in the Dominion, to have carried the interest and character of the profession to its present high respectable place, the meeting could understand that he (the President) acceded to the discharge of his duty with some trepidation. It became apparent twenty-six years ago to the fathers of medicine in the country that it would be a wise thing to unite the ablest of the best elements of medicine in Canada, so that in unity they might advance to material progress, that they might ever defend themselves against the inroads of charlatanism and scepticism, so ready to scoff at true scientific judgment, and by cultivating friendly feeling and advancing special lines of work they could attain to a measure of progress which would be mutually beneficial.

In alluding to the grand results arising from the Association, Dr. Sheard said that when it had set an impermeable front, which only the boldest and rudest would attempt to attack, when it was of still more value to younger men, when it had left an example which would live long after the oldest members had passed away, surely it could be said that the Dominion Medical Association had not lived in vain.

Reference was made to the names of some of the past presidents of the Association; men, who had left behind them a character and an example, which every young man starting out in his profession ought to remember. Unfortunately there was a growing tendency for the younger man to assume that it was reserved for him to know all the best and most improved methods of scientific discovery, and while some of these might not be as familiar to his older colleagues, and while some of them might be occasionally paraded in an uncalled-for manner before a less informed patient, jealousies were apt to arise, which as time advanced tended to prevent that harmony of feeling which should prevail between professional colleagues.

"As there should be unity among the members of the profession in Canada, so there should be some unity of privilege," continued the President. "It appears to me scarcely conducive to professional unity that we should have in the various Provinces of the Dominion separate licensing bodies, which confer the privilege of practising only for the Province, and that those of us who may today reside in Ontario in travelling to Manitoba or British Columbia require there to pass a period of naturalization before we can even be examined, and have then to pass again an examination which proves our qualification to practise—and this in our own country. Surely we are all Canadians, and if the spirit of the times means anything, we are united in patriotic feeling and national progress. Why should it be different in medicine? I may express the earnest hope that the time is not far distant when there will be some central examining board or boards for the whole Dominion, when a license from such a body will be a qualification to practise from one end of the country to the other."

Alluding to the subject of medical progress, Dr. Sheard said, "The practice of medicine in the last decade has been more particularly signalized by the advancement of pure science, and the science of bacteriology has now become a science of diagnostic medicine.

"In the diagnosis of tubercle the bacterial examination of the sputa in phthisis is quite as correct diagnostically and more certain than the examination of the skilled auscultator. In the diagnosis of Asiatic cholera the most expert physician waits for the deliberation and revelations of the bacteriologist, and in many other ways we see the practical results and usefulness of scientific advancement. It has been the history in the past for diagnostic principles to precede curative measures, and I entertain little doubt that those of us who are spared another ten years may see a solution to the difficulty which besets the cure of phthisis, and such diseases whose causation within the last decade has been so clearly demonstrated.

"Science and practice of medicine go hand in hand, as science and art everywhere. Science smoothes the ground for art to follow, never antagonistic, ever in unison.

"We must ever guard against the tendency to separate the science of art and medicine. The more advanced methods of observation, the carefulness and delicacy of manipulation, requisite in handling scientific apparatus, render it in a measure imperative that one who adopts the scientific fields of labor must withdraw from active practice.

"The physiologist must not only understand the most sensitive electrical apparatus and electrical law, but he must be also a mechanic, a careful dissector, and a man of marked ingenuity. Truly, as Oliver Wendell Holmes said, the greatest, broadest, the most mutual and attractive of sciences is physiology. The noblest study of mankind is man. So in chemistry the details of chemical experiment and the field of chemical investigation are so distinct from the ordinary work of a surgeon that perforce it must be left to the surgeon to proceed upon data separated by chemistry, and when we come into the modern revelations of bacteriology, the preparation of the bacteriologist's media, the careful knowledge of chemistry embodied in his work, the study of air-plates and air-forms, and delicate micro-organisms common to the atmosphere in which he works, the character of this and that product common to his special class, all tend to leave the obverse and reverse of medicine's medal distinct. We must do our part as practical physicians to harmonize and combine these lines of observations if we wish for material advancement. Koch was a general practitioner, Watson Cheyne a consulting physician.

"It is sometimes to the credit of a young country like ours to be able to say that on these lines of scientific attainment Canadians are fully abreast of the times, while we may yet be lacking in men of marked original research. This is not due to lack of intelligence and energy. The development of genius is endemic; it is allied to the friction of mind with mind; it is developed by criticism and comparison, possessed with a desire to excel, until at last it lays bare a truth which startles the world and benefits mankind everywhere."

Dr. Sheard concluded an eloquent and brilliant address by urging the desirability of medical men in Canada being united in everything calculated to advance the interests of the profession throughout the Dominion.

Nominating Committee.—The nominating committee was appointed as follows: Drs. Stewart and Roddick, of Montreal; Graham, McPhedran and McCallum, of Toronto; Harrison, of Selkirk; Holmes, of Chatham; Bucke, of London; Olmstead, of Hamilton; and Fulton, of St. Thomas.

Dominion Registration.—A committee was appointed to consider the subject of Dominion Registration which had been alluded to in the president's address.

The following interesting papers were read. "Some Unusual Conditions met with in Hernia Operations," by Dr. James Bell, of Montreal; "Causes of Blindness in Ontario," by Dr. Osborne, of Hamilton; "Sanitary Science—Some of its Features," by Dr. Canniff, of To-

ronto. "A Case of Pernicious Anæmia," by Dr. Olmsted, of Hamilton.

Puerperal Eclampsia.—Dr. J. Campbell, of Seaforth, presented an interesting paper on "Puerperal Eclampsia." After briefly reviewing the various causes which are generally supposed to provoke eclampsia in the pregnant, he gave a report of a recent case. The patient was pregnant for the eighth time and was at the time seven and a half months advanced. She was taken with severe headache, and felt a beating like a hammer in the head. There was also pain in the left shoulder and neck. The first convulsion was at 2 A.M. He gave a dose of elaterium and one drachm of chloral hydrate by enema, which induced sleep for several hours. Another convulsion followed shortly after waking, although the elaterium was then moving the bowels freely. The chloral was repeated and cold cloths applied to the head. This was followed by another sleep, and on awakening she was given a diuretic mixture containing acetate of potash and tincture of digitalis, but the stomach would not retain the medicine. The urine was literally solid with albumin. As another severe convulsion followed it was decided in consultation to bring on labor. The os was found to be slightly dilated, and the membranes were at once ruptured. Labor pains soon followed and under the influence of the chloral the patient slept most of the time. Natural delivery followed in a couple of hours afterward, a dose of ergot being given shortly before the birth. There were no convulsions after delivery. The diuretic mixture was continued, and the albumin gradually disappeared from the urine.

Dr. Campbell concluded his interesting paper by emphasizing the following indications for treatment in such cases: 1. To eliminate the septic matters from the blood as rapidly as possible. 2. To diminish the sensibility of the nervous system and decrease muscular power. 3. If convulsions come on during labor to save the infant without adding to the risk of the mother. 4. To guard the mother from injury during the attack.

Dr. Lapthorn Smith, of Montreal, questioned the fact of there being an anæmic condition of the brain in this disease. He thought the brain was congested.

Dr. Wesley Mills, of Montreal, defended the theory of anæmia.

Dr. Irving, of St. Marys, said he had his doubts about using ergot just before delivery.

Dr. Bethune, of Seaforth, had seen the case related by Dr. Campbell, and testified to the severity of the convulsions and his accordance with the treatment so successfully followed.

Dr. Campbell concluded the discussion by briefly replying to some questions that had arisen.

The General Practitioner and the Insane.—Dr. J. V. Auglin, of Verdun, Montreal, presented a paper on this subject. He discussed the elementary principles of treatment for the insane and ably reviewed some of the improved methods of dealing with these cases. The asylum was now as free from objectionable features as the hospital. The attendant was no longer a keeper, but the patient's companion.

Is Alcohol in all Doses and all Cases a Sedative and Depressant?—Dr. S. T. F. Harrison, of Selkirk, in an interesting paper, discussed the question. A number of cases were cited to show how through the free use of alcohol some apparently hopeless cases had been saved. Particularly in fevers and diseases of a septic origin had he found alcohol a most valuable agent.

Dr. Arnott, of London, claimed that alcohol was not a stimulant, but an anodyne, and instanced cases where he had used chloroform with good effect where whiskey was generally given.

Dr. T. W. Mills, of Montreal, totally disagreed with the opinions expressed by Dr. Arnott. He regarded alcohol as a most important remedy in some cases, and expressed his disapproval of the present text-books on temperance used in the schools.

Address on Surgery.—Dr. W. H. Hingston, of Montreal, gave an instructive address on Surgery, in which he reviewed the history of several operations.

Displacement of the Kidney.—Dr. F. R. Eccles, of London, read a paper with the above title.

In the discussion which followed, Drs. Ball and Lapthorn Smith, of Montreal, spoke of the abuse of corsets by women as a frequent cause of displaced kidney, and cited a number of examples coming under their notice, illustrating some peculiar symptoms arising from this trouble.

Dr. H. S. Berkett, of Montreal, presented a paper on "Thyrotomy for Large Sub-cordal Spindle-celled Sarcoma," with an interesting case.

Dr. Osborne, of Hamilton, and others followed in the discussion of the case.

The Banquet.—The members of the Association were entertained at a banquet in the evening by the members of the medical profession of the city of London. The chair was occupied by Dr. George Hodge, of London, and the postprandial speeches which followed were of a high order.

Second Day, Thursday, September 21st.

The Address on Medicine.—Dr. A. McPhedran, of Toronto, delivered the annual address on Medicine, which was followed by an interesting discussion.

Cholecystostomy.—Dr. Ferguson, of London, read a report and presented a case of successful cholecystostomy, which had required three operations. The patient was a young married woman, and in the course of treatment eighty gall-stones were extracted.

Dr. Primrose, of Toronto, read a highly interesting paper on "The Anatomical Relations of a Large Malignant Growth in the Neck with a Secondary Deposit in the Lung."

"Two Cases of Laparotomy for Unusual Conditions" was the subject of an interesting paper by Dr. T. K. Holmes, of Chatham.

In the Medical Section Dr. Arnott, of London, read a paper on "Some of the Uses of Sulphurous Acid," and Dr. McKeough, of Chatham, on "The Prophylaxis and Treatment of Puerperal Eclampsia."

Dr. McCallum, of London, and others also contributed highly interesting papers.

Friedreich's Ataxia —Dr. George Hodge, of London, presented three interesting cases of Friedreich's Ataxia—two sisters and a brother. There was no history of a similar disease, or of any nervous disease in the ascendants. Patients are aged respectively forty-one, thirty-seven, and thirty-five. In each the disease began at about the age of thirty-one. The chief symptoms common to all the cases are: Reeling on standing, even with eyes open; worse when eyes are closed; inability to walk across the floor without support; while sitting or lying down all ordinary movements of the legs can be performed; little or no muscular wasting; sensibility in legs to touch, pain, and temperature normal; muscular sense normal; superficial reflexes normal; no ankle clonus; patellar reflexes markedly increased. There was talipes varus in all the cases, also lateral curvature of the spine. There was nothing abnormal in the upper extremities, except that in the youngest patient the hands are claw-shaped, with marked wasting of the thenar and hypothenar eminences and also of the interosseii. Pupils react normally; marked horizontal nystagmus; all organs of sense normal. There was little if any change of speech, and the intelligence was unaffected.

An interesting discussion followed.

A Luncheon Party.—By invitation of Dr. Bucke, Medical Superintendent, the members of the Association paid a visit of inspection to the London Asylum for the Insane. After being conducted through the buildings and grounds the attention of the visitors was directed to the recently constructed sewage system, which is giving excellent satisfaction. An elegant lunch was afterward served.

Alcohol for the Insane.—In the course of his address after lunch Dr. Bucke said that when he came as superintendent to the Asylum, seventeen years ago, they were in the habit of using $4,000 or $5,000 worth of alcoholic liquors in the dispensatory department each year. His predecessor thought alcoholic stimulants were absolutely indispensable for the patients. The experiment of stopping it was tried, but the death rate increased and they fell back on the old practice. In his first year as superintendent the liquor bill was, however, reduced to $600 a year. For twelve years no alcoholic liquor has been used in the Asylum, and the death rate has been reduced from five to 4.3 per cent., and the recoveries have been over three per cent. more. For ten years restraint has been discontinued in the care of new patients. They found the employment of the patients about the grounds and buildings very beneficial. The good effect of amusements, the introduction of music, and the training of an orchestra were referred to as most helpful to the patients. During last season they had 110 evenings of amusement, of which 44 were dances, 25 "at homes," 18 lectures, and the remainder concerts. The buildings are kept in a thoroughly sanitary condition, and among the many hundreds of patients there was comparatively little sickness.

A number of interesting addresses followed, indicating the pleasure the members of the Association felt in thus being afforded an opportunity to visit and inspect one of the largest asylums in Canada.

Evening Session.

Dr. Praegar, of British Columbia, presented the report of the Committee on Medical Registration. He recommended a scheme by which a physician of one Province may practice in any other through the agency and authority of a Dominion Medical Examination Board, a supreme organization for Canada. The report also suggested co-operation between England and Canada.

Dr. A. B. McCallum, of Toronto, said he had little hope of securing such a result in this generation. Medical practice came under Provincial jurisdiction, and some universities did not give medical degrees. While there was such a difference of views in Quebec as to the curriculum, so long would the present anomaly in that province exist. The report would give the privilege of conferring degrees to Laval and other Quebec universities while withholding it from some in Ontario. He suggested that the universities send delegates to this Association to devise a united plan of action. The matter was then by motion allowed to lay on the table for another year.

Some Peculiar Forms of Sleep or Allied Conditions.—Dr. T. Wesley Mills, of Montreal, read an interesting paper on this subject. He referred to published reports of people going into trances or long sleeps, which at one time he could not believe, but with age and experience he was forced to conclude that there were good foundations for most popular beliefs or delusions. He had watched the hibernating habits of a woodchuck for four years. He had also studied three or four authentic cases that had occurred in Canada, the subjects of most of them being weak-minded, with often hereditary symptoms of insanity. Some of the individuals slept for months or years, some of the circumstances being similar to the case of the woodchuck—the taking of food and the attending to calls of nature at regular intervals, in one case thirty days, during the term of sleep of hyperbernation, six months every year for thirty years. In the case of one, an old woman, who died at the age of seventy, one third of her life was spent in a stupor. She asked for a drink of water shortly before her death, which was the second time she had broken silence for thirteen years. As death approached she recovered partial consciousness, and manifested affection to one of the nurses and spoke more frequently.

Dr. A. B. McCallum, of Toronto, inquired if Dr. Mills wished to be taken as a believer in Rip Van Winkle. He pointed out some radical differences in the symptoms of the different cases, and argued that while they might have arisen from analogous causes, the hybernation of the animals was attended with a different condition of the nerve cells. The subject was interesting and he considered the paper a highly interesting one.

Dr. R. A. Reeve, of Toronto, followed with an instructive paper on "Ophthalmic Memoranda," and Dr. D. C. Meyers, of Toronto, with a paper on "Multiple Neuritis."

Election of Officers.—The report of the Committee on Nominations was presented and the following officers elected: *President*, Dr. Harrison Selkirk, of Ontario; *General Secretary*, Dr. Starr, of Toronto; *Treasurer*, Dr. Small, of Ottawa; *Vice-Presidents*, For Ontario, Dr. Eccles, of London; for Quebec, Dr. Stewart, of Montreal; for New Brunswick, Dr. Christie, of St. John; for Nova Scotia, Dr. Muir, of Truro; for Manitoba, Dr. Spencer, of Brandon; for Northwest Territories, Dr. Newburn, of Lethbridge; for Prince Edward Island, Dr. Taylor, of Charlottetown; for British Columbia, Dr. McKecknie, of Nanaimo; *Local Secretaries*, for Ontario, Dr. Olmstead, of Hamilton; for Quebec, Dr. Anglia, of Montreal; for Nova Scotia, Dr. McKeene, of Cowe Bay; for New Brunswick, Dr. McLaren, of St. John; for Prince Edward Island, Dr. Johnston, of Charlottetown; for Manitoba, Dr. McDermitt, of Winnipeg; for Northwest Territories, Dr. Calder, of Medicine Hat; for British Columbia, Dr. Walker, of New Westminster.

The next meeting of the Association well be held in August, 1894, at St. John, New Brunswick.

A complimentary resolution was unanimously carried, expressing the appreciation by the members of the Association of the hospitality they had enjoyed during the meeting in London.

Therapeutic Hints.

Neuralgia. — Hypodermic injection of the following solution has been found valuable by Crocq. One cubic centimetre is employed at first and gradually increased to three.

Phosphate of soda	gram. 2
Alcohol	" 5
Sterilized water	" 100

Hydrotherapy in all possible forms of chronic nerve troubles gives extraordinarily favorable results. There are few remedies which have an equally powerful influence upon the nervous system.—Erb.

Sodium Phosphate in two per cent. solution, with defibrinated blood, was used for transfusion in a case of pernicious anæmia, with favorable results.—Evans.

Basedow's Disease.—Intestinal antiseptics. Tincture of strophanthus as a vaso-motor tonic, restricted meat diet, fermented milk substituted.—Thomson.

Impacted Fæces can be removed by galvanism applied within the rectum, when other means fail.—Soutakis.

Headache.—When the pain is frontal and close above the frontal sinuses, dilute nitro-hydrochloric acid in small quantity, added to a moderate dose of antipyrin or other analgesic, subdues the pain more rapidly than any of these drugs separately.—Gillespie.

Lupus Erythematosus.—Iodoform and medicinal soap, each ten centigrammes, taken in pill form twice daily, may do good.—Besnier.

Methyl Violet given in capsule has been found curative in certain cases of cystitis.

Mercurial Flannels which give off mercurial vapors have been advocated in the treatment of syphilis.

Gonorrhœa.—

Bismuth subnit.	gram.	5
Quinine sulphat.	"	1
Aquæ rosæ.	"	130

Use as injection.

—HAMONIC.

Lichen planus, with intense pruritus and nerve disturbances, has been relieved by Jacquet with the hot douche.

Late Ocular Manifestations of syphilis are treated by sub-conjunctival injection of one drop of a one to one thousand solution of corrosive sublimate.—ABADIE.

Otalgia.—

Menthol	ʒj.
Camphor	ʒj.
Liquid vaseline	ʒj.

Instil into the ear several times a day.

—*Medical Press.*

Treatment of Diphtheria.—

℞. Phenic acid	ʒij.
Salicylic acid	ʒiij.
Benzoic acid	ʒj.
Proof spirit	ʒiv.

A tablespoonful in two quarts of boiling water to steam the room of the patient. It should be renewed every three hours.

Green soap	"	10
Axunge	"	20–30

Apply a thin layer for an hour or two at night to half the face at a time. Wash off with hot water, and then powder the surface. After a week or two apply an ichthyol ointment.

—SCHWIMMER.

Blennorrhagic Cystitis.—From all points of view, nitrate of silver possesses an incontestable superiority over other therapeutic agents.—DESNOS.

Psoriasis.—The application of chrysarobin in chloroform (1 to 10) was found to be the most successful treatment.—HAUMER.

Oil is preferred by Burlureaux to all other excipients for the subcutaneous injection of remedies. Besides being readily digested in the skin, it is in itself a food which can only be beneficial.

Iodoform, with its double action of anæsthesia and analgesia, is highly praised by Mosetig in the treatment of burns.

Beware of infecting the posterior urethra by too forcible injections.—BROCQ.

Intestinal Flatulence.—

Powdered coriander Powdered peppermint Powdered vanilla	each, 5 parts.
Powdered senna	1 part.

A teaspoonful 2 or 3 times a day.

—MONIN.

Chronic Tonsillitis —

℞. Acid. tannic.	gr. 15
Tinct. iodinii	gtt. 2
Aquæ	ʒ 6
Glycerine	ʒ ½

M. Sig.:—Tablespoonful every three hours.

Neuralgia.—

℞. Acetanilid	gr. 1
Quinine	" 1
Cocaine	" 1/10

For one pill. Give every hour.

Asthma.—

℞. Ether	ʒ 1
Oil of turpentine	ʒ 4
Benzoic acid	ʒ 4
Balsam of tolu	ʒ 2

To be inhaled during an asthmatic attack.

—*The Doctor.*

Simple Remedies for Constipation.—A tart apple eaten before breakfast and followed by a glass of cold water, with a regular time for morning stool, preferably within one hour after morning meal. Oftentimes a simple glass of cold water, to which is added a pinch of common table salt (sodium chloride, five grains or less), drank before breakfast, will produce the desired effect.

Aperient for Occasional Constipation.—Occasional attacks of constipation are often promptly relieved by a pill composed of one-half grain of calomel, two grains of extract of aloes, and one grain of extract of hyoscyamus, followed in the morning before breakfast by two drachms of sulphate of soda in a tumblerful of hot water. It may be necessary to follow this treatment for three or four mornings with a Seidlitz powder on rising.

An Excellent Pill for Chronic Constipation.—

℞. Aloinæ	gr. iv.
Strychninæ sulph.	gr. ½
Ext. belladonnæ	gr. i½.
Pulv. ipecac.	gr. vi.

Mix and divide into twelve pills, one nightly.

Coughing made Easy in Bronchiectasis and Phthisis.—Large cavities are often easily emptied by taking advantage of gravity and coughing with the head and chest at a downward angle. The patient can lie on bed or lounge, lean over the side, resting on the hand and lower the head as low as convenient during the coughing spell. The pocket of secretion is thus inverted, and the period of paroxysm materially lessened. Mr. N. P. Willis, the poet, who thought out this method for himself, called it "coughing down hill."—DR. H. D. DIDAMA, Onondaga, N. Y.

Treatment of Acute and Chronic Rheumatism.—For the last six years M. Ruel has treated externally only acute or chronic rheumatism. Compresses steeped in the following solution are applied twice a day to the articulation, and covered with oil-silk so as to prevent evaporation :

℞. Salicylic acid	ʒ v.
Proof spirit	ʒ iij.
Castor oil	ʒ vij.
Chloroform	ʒ iv.

When the applications are properly made the salicylic acid appears in the urine twenty-four hours after.—*Medical Press.*

Recent Coryza.—

℞. Morphine hydrochlorate	gr. 2
Pulv. acacia	ʒ 2
Bismuth subnitrate	ʒ 6

Use as snuff.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

END OF THE LONG VACATION—INFECTIOUS DISEASE IN LONDON—SCARLET FEVER AND DIPHTHERIA—THE CHOLERA—SIR WILLIAM JENNER'S VOLUME OF LECTURES AND ESSAYS—ZOLA IN LONDON—DEATH OF THOMAS HAWKSLEY, C.E., F.R.S.

SATURDAY, September 30, 1893.

THE end of the vacation has arrived. On Monday the medical schools open for the winter session, some of them maintaining the time-honored "Introductory Lecture," while others have embraced a new departure. In anticipation of this event most of the teachers have been in town several days, and the few who remain away to the latest hour will turn up this evening or Monday morning. Of course there has been no lack of doctors in London during the vacation. An exodus of teachers and well-to do or fashionable physicians makes little impression on the array of practitioners who do most of the work—in fact, it no more than corresponds with the flitting of the richer classes. But the return corresponds with a livelier feeling in professional circles and the hope, if not the expectation, of improved practice. Following closely on the schools the medical societies will soon be beginning their sessions, and we shall be plunged into the excitement of free discussions and full work for the winter evenings.

There is an unusual amount of infectious disease in London just now, and the Asylums Board is feeling the pressure more severely than perhaps at any time previously. A new hospital is being built at Tooting, and two others, it is hoped, will be begun at once, as well as a fresh convalescent hospital, a few miles out. I am informed that the cases of fever continue to come in from all districts, and last week every parish contributed to the total of 3,153 under treatment. Only the most urgent cases can be admitted as the discharges take place. Thus about sixty cases per diem are provided for, while the notifications have run up to 400 per diem. One day indeed the discharges only permitted the admission of 35 urgent cases of scarlet fever. It is this disease which is crowding the hospitals. Many of the cases are mild, but the need of isolation, the impossibility of many obtaining it in their homes, and the growing confidence of the people, combine to increase the pressure faster than has been expected. Diphtheria furnishes fewer cases, but their mortality is much higher. The mortality of scarlet fever in hospital cases seems to have somewhat declined, but this is probably because a larger proportion of milder attacks are now removed to the hospitals, and the fact suggests further pressure on the hospitals in future epidemics.

Cholera has been still kept at bay during the past week. On Thursday afternoon the Local Government Board reported that no death had occurred in England and Wales during the preceding twenty-four hours. Last night the official bulletin announced that only one death at Hull and one at Great Yarmouth had occurred. One or two suspicious cases elsewhere will be examined by experts. A steamer from Cronstadt arrived off Gravesend with one case, which was promptly removed to hospital, and every precaution taken, with the result that it has not spread. The expert could not distinguish it from true cholera.

Sir William Jenner's promised volume has appeared. It is entitled "Lectures and Essays on Fevers and Diphtheria, 1849 to 1879," and consists entirely of previously published matter. There is no attempt to bring the contributions down to date, and they must consequently be read as representing the author's work and opinions at the time they were first issued. In some respects this will be an advantage to the younger men who are too apt to confine their views to the latest exposition of facts, and so have very indefinite notions as to the historical development of the prevailing ideas and methods. Most of the work consists of the learned author's contributions on fevers, opening with those in the *Edinburgh Monthly Journal* of 1849–50 on the "Identity or Non-Identity of Typhoid and Typhus Fevers." The subject is continued in the paper submitted to the Royal Medical and Chirurgical Society about the same period. Appended to this is the debate that ensued, and which will be read with interest by many. Sir William Jenner was by no means the first to suggest the differentiation of these fevers, and he makes no claim to priority. He, however, did so much to establish the doctrine that many have credited him with the discovery of what had been propounded before. He is detailing his own work and conclusions and does not profess to go into the history of his subject. He is, therefore, not obliged to discuss the origin of the doctrine he espoused, and indeed he mentions some observers to whom he was indebted. I think, however, it would have been interesting to readers, and honorable to the author, to have expressed by way of note or supplement, his views on the efforts of those of his predecessors and contemporaries who saw more or less clearly and taught fearlessly the truth of the doctrine he succeeded in establishing. In the Gulstonian Lectures of 1853, Sir William Jenner gives a charming account of the manner in which the differentiation of these and other fevers and the exanthemata was gradually brought about during the last two centuries. The remainder of the volume is occupied by reprints on "Croup and Diphtheria," 1861 and 1875. These more recent contributions would have to be little, if at all altered, if the author decided to edit them so as to express his present views. Altogether this handsome volume is a goodly addition to the library; but as it consists only of reprints of articles with which I was familiar I cannot indulge in the ecstatic gratitude to the author which some of your contemporaries here already express.

Writing of books, I may mention that London authors have been all the week fêting Zola, and, of course, some doctors think they must read something of the great French novelist. His "Doctor Pascal" has therefore a chance for a run. The writings of this realist some years ago brought a prosecution on the publisher of a translation, but his talent has enabled him to attain the highest distinction in his own country, and now English novelists honor him as a representative of French literature; but I wonder how many allow their daughters to peruse his works. The death of Thomas Hawksley, F.R.S., may be mentioned here, although he was not a medical man. He was an engineer, and as such the designer of many sanitary undertakings. Water supply was a great specialty with him, and it is said he constructed more than one hundred and fifty waterworks. Some of these were enormous undertakings. He adds one more to the many scientific men, personally known to me, whose deaths I have had occasion to report, and whose place it will not be easy to fill.

TYPHOID FEVER—ITS DE NOVO ORIGIN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The article in the MEDICAL RECORD of September 9th, by Dr. Hubert Work, on "Typhoid Fever, Its De Novo Origin," calls to mind a case that occurred in the mountains of Montgomery County, Va., some years ago. I have no notes on it and will not attempt to detail the symptoms. Suffice it to say its cause was typical, and ended in the recovery of the patient, a man under middle age. Among other characteristics were great prostration, continuous delirium for days, and intestinal hemorrhage. I want to call special attention to the circumstances that preclude any possibility of contagion, or the use of contaminated water, certainly any water infected with special typhoid germs. This man lived on the mountain side, the approach to his house or cabin

being so steep that one had to tie his horse and climb several hundred feet. The history given was that he had been very closely at home and had not been out of the neighborhood for weeks. The water-supply was from a mountain spring. Drainage was apparently perfect, and he breathed the purest of mountain air. At the time there were no other cases in the neighborhood. The family continued to use the spring water, and no other cases developed.

I have been puzzled over and over again to understand why we have cases of typhoid fever at all in the mountains, if it originates almost exclusively from the water-supply. This case, however, furnished less explanation than any I have ever met as to its origin. There is certainly a defect somewhere in the reasoning of the germ-theorists and bacteriologists, who would confine us to a specific cause for everything. Given pure spring water, mountain air, and perfect drainage, where do the germs come from that will cause a sporadic case here and there in a family, when there has been no possibility of previous contagion and no further cases develop, although wife and children continue to drink the same water and breathe the same atmosphere? This is no unusual history in this section.

Yours truly,

W. R. CUSHING, M.D.

DUBLIN, VA., October 6, 1893.

IMMUNIZING FOR YELLOW FEVER.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The immunizing method of Dr. Murray, given in your number of October 7th, seems to me quite correct. However, I should propose the following modifications; you will find them in perfect accord with the idea of Jennerean vaccination, which certainly should guide us. They are corroborated by my own experiments with scarlet fever:

1. Instead of carrying the patient to the infected region, take the infection to the patient; that is, inoculate him with the blood-serum of a partially immune subject of yellow fever, a half- or quarter-blood negro, for instance, and inoculate him a second time, forthwith, with a white blood-serum perfectly immune, that is, belonging to a white subject who has had yellow fever.

2. Or; wait until frost appears, which always modifies the virus, or expose the infected blood-serum to frost, before inoculating it, and follow this at once with a second inoculation of immune blood-serum.

Sincerely yours,

ALBERT S. ASHMEAD, M.D.

45 MACDOUGAL STREET, NEW YORK,
October 7, 1893.

Athletics and Appendicitis.—Dr. C. F. Crehore offers, in the *Boston Medical and Surgical Journal*, a suggestion accounting for the present prevalence of appendicitis. Looking beyond food and clothing as etiological factors, he finds in one particular a condition of recent origin which may possibly explain, in some degree, the frequency of the disease. This is "the comparatively recent and very general introduction of methods of physical culture and the resultant growth of athletic sports. Calisthenics, as generally taught, appear harmless enough; but many of the postures involved cause a good deal of abdominal pressure. It goes without saying that where an overloaded colon is subjected to such pressure, a portion of the fluid matter entering from the ileum might be forced downward into the appendix and be the cause of serious disturbance. The danger from such a contingency would naturally be increased in the more violent gymnastics and the rougher athletic games—as baseball or foot-ball, rowing, polo, and the like. The position of the modern bicyclist when riding, seems very favorable to an injury of that description."

New Instruments.

AN INSTRUMENT FOR THE RHYTHMICAL EXERCISE OF THE OCULAR MUSCLES—THE PHOROTONE.

BY H. MCI. MORTON, M.S., M.D.,

PROFESSOR OF CLINICAL OPHTHALMOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, MINNEAPOLIS, MINN.

EXERCISE of the ocular muscles in certain forms of asthenopia has, on this side of the Atlantic, been recognized for some time as a most valuable therapeutic agent. It was until lately the practice to place before the eye a prism of certain strength, with its apex toward the weak muscles, allowing it to remain in this position for a few minutes, with the eyes fixed upon a candle-flame twenty feet distant. It is an enigma to me that the illogical and unscientific principles underlying this plan were not pointed out much sooner than has lately been done by Dr. Savage, of Nashville. This method excited and fatigued, rather than exercised, the insufficient muscles. An athlete in the development of his biceps does not *hang* upon a pair of parallel bars, but, by *alternately contracting* and partially or completely relaxing, seeks to give strength to the organ.

Before the article by Dr. Savage appeared in the *Ophthalmic Record* these thoughts had very forcibly presented themselves to me, and while practising this

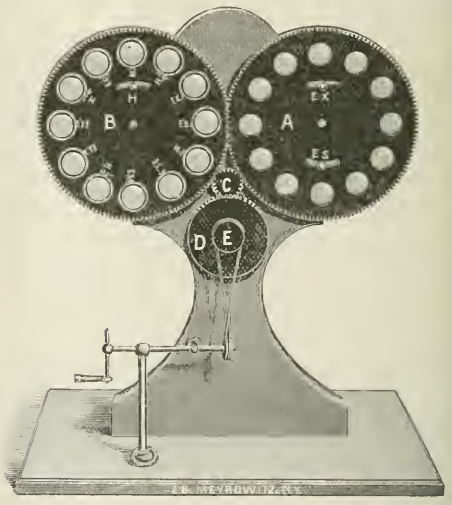

FIG. 1.

method I have for some time been impressed with the primitive as well as awkward manner of its application. So far the only manner of applying these exercises is as described by Dr. Savage:

"The prisms to be used may be from one-half degree to four degrees, and one should be placed before each eye. The treatment should be commenced with the weaker prisms; and, as development of the muscles advances, the stronger should be brought into use. The object looked at should be a candle, lamp, or gas-jet, fifteen to twenty feet distant. The prisms before the eyes, the image in each of the eyes is displaced out and the guiding sensation calls quickly into action the interni. After five seconds the interni must be allowed to relax for the same length of time (five seconds), which is *readily effected by lifting the prisms up and allowing the light to enter the eyes uninfluenced.*[1] The guiding sensation at once causes the relaxation to take place, so that the yellow spots may receive the image. At the end of

[1] Italics mine.—H. MCI. M.

this five seconds the prisms are again dropped before the eyes, and the interni again contract."

By this method it is very difficult to have prisms of gradually increasing and diminishing strength held before the eye, and also to regulate the periods of exercise and rest. It also takes time, and if practised upon a number of patients in one day gets very wearisome to the oculist. Having fully appreciated these disadvantages in the past eight months, I attempted, and think have succeeded in overcoming them by the instrument

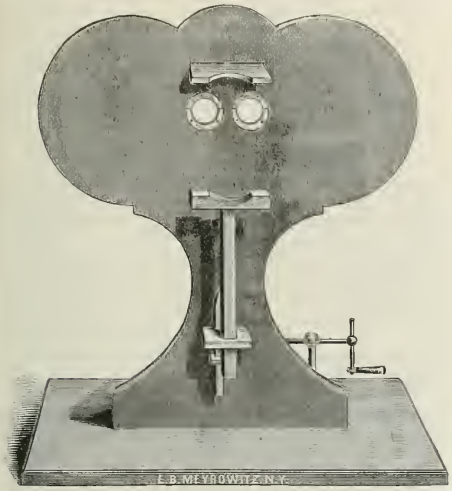

FIG. 2.

which I shall describe, and the front view of which is illustrated in Fig. 1. The patient may, by simply turning the handle, exercise his muscles without the attention of the oculist. By a simple matter of turning the small knob at the points marked Es, Ex, and H, any set of muscles may be exercised, or all, at the same revolution of the disks. The instrument consists of two revolving disks, A and B, propelled by a small cog, C, which in turn is moved by the quarter cogged wheel, D, connected to the shaft by a belt. The disk B (or "exercising disk") contains twelve prisms, *i.e.*, three sets of four prisms each, so arranged that one set exercises the interni and one the externi; another, the superior and inferior recti muscles. Back of this disk is another one (see Fig. 4), containing eight prisms, so arranged that by a movement of the small knob at H, the esophoric and exophoric prisms in B are neutralized, thus permitting exercise of the superior and inferior recti. The disk A contains

FIG. 3.

FIG 4

openings corresponding to those in disk B, but without prisms. Back of this A disk are two disks, G and H (Fig. 3), containing neutralizing prisms. Thus by moving the knob at Ex, all the prisms in B are neutralized, but those to exercise the interni. The same by the knob at Es, thus working the externi. By allowing all the neutralizing disks to be out of use, all of the recti are exercised alternately. Thus when working one set of muscles, we have one period of exertion to two of rest, which I think a proper ratio. If desirable, instead of having all of the exercising prisms in B, we may divide the strength between A and B. Thus, instead of having one three-degrees prism, base out in B, we may have two of one and one half degrees, base out, in each A and B. It might be suggested that a disk so arranged over B as to cut off all openings but those to be used would answer better than neutralizing prisms, and be cheaper, but this would be equivalent to closing the eyes in the two rest periods, following upon the exercise period, and, as Savage says, "When the eyes are closed, relaxation is slow to take place, and is rarely completed at the end of sixty seconds." Thus it is essential that the eyes look at the distant object (the candle-flame at twenty feet) after they have fused the double image, in order to immediately relax them. It is obvious that continuous movement of the disk is not desired, and a period of rest is obtained by having the wheel D quarter-cogged only, so that during three-quarters of the time it is in motion, C is at rest. The patient, by steadily turning the handle, has uniform periods of contraction and relaxation of the muscles. In the back of the instrument (see Fig. 2) are two clips to hold supplementary prisms if desired, also a movable chin-rest, which permits adjustment to suit the patient. Disks containing cylinders for exercising of the obliques may be added if desirable.

I feel greatly indebted to Mr. E. B. Meyrowitz for much valuable advice and assistance, many points of improvement being suggested by him.

51 AND 52 SYNDICATE BLOCK, MINNEAPOLIS.

A NEW HOLDER FOR SIMS'S SPECULUM.

BY B. H. DAGGETT, M.D.,

BUFFALO, N. Y.

VAGINAL specula are older than the everlasting hills, and their origin is enveloped in the mists of antiquity. Saranus and Paul of Ægina allude to them, and they have been found in the ruins of Herculaneum and Pompeii. The fame of their discoverer and patentee is shrouded in the dust of centuries; his name is unknown, unhonored, and unsung. The improvements devised by Récamier and Fergusson gave an impulse to the evolution of tubular specula, and their use for caissoning the vagina became general within the past century.

Following the introduction of stovepipe specula, came an epidemic of valvular peek-a-boos, fearfully and wonderfully made. Through the open spectacular way maintained by these instruments, the assault upon the innocent, retiring womb began with puncture, incision, cauterization of the os tincæ, and was carried onward through the via vitæ, fraying the fetal abode with sound curette, and drenching it with medicament.

No man can estimate the amount of injury and suffering caused by sounds, and cylindrical and valvular specula in the hands of the injudicious, indiscriminate, gynecological tinkerer. The internal viscera, being endowed with a minimum degree of sensibility to the pain of traumatism, and their abnormal processes being generally sluggish and insidious in their course, these storm-signals are obscured and overlooked, until the skilled hand of the specialist reveals the presence of intrapelvic disease or the nerve counterfeits of uterine disorder. Says Van de Warker: "The misery inflicted upon women by these instruments is an unwritten chapter in human suffering."[1]

Joseph Price affirms that cylindrical and valvular specula do harm in the hands of the inexpert, and the expert do not need them; that if ocular examination is to be made, or local treatment is indicated, the lateral position and the Sims speculum should always be employed.

Matthew D. Mann always employs the lateral position and the Sims speculum, except when making bimanual examinations and performing certain operative procedures. His writing, teaching, and practice confirm this

[1] MEDICAL RECORD for April 18, 1893.

statement. These references suffice to indicate the opinion of gynecologists concerning the use of valvular and cylindrical specula.

The impediments which bar the general employment of the lateral position and the Sims speculum may be readily overcome, and are named as follows:

1. The want of tact and experience in the necessary manipulation. The remedy is obvious.

2. The necessity of a proper posture, as the Sims speculum will not provide or maintain an open way to the vaginal depths, except a depressor is also used, or the pelvis be raised sufficiently to relieve visceral pressure by gravitation. To obtain visceral prolapse the patient is tilted from the lateral to a semi knee-chest posture, the body being supported by the knees, left thigh and chest, and the lateral pelvic plane being at an angle of forty-five degrees with a horizontal line. This position gives all the benefits of the lateral and knee-chest postures without the discomfort of the latter. The KNEE-THIGH CHEST posture is illustrated in Fig. I.

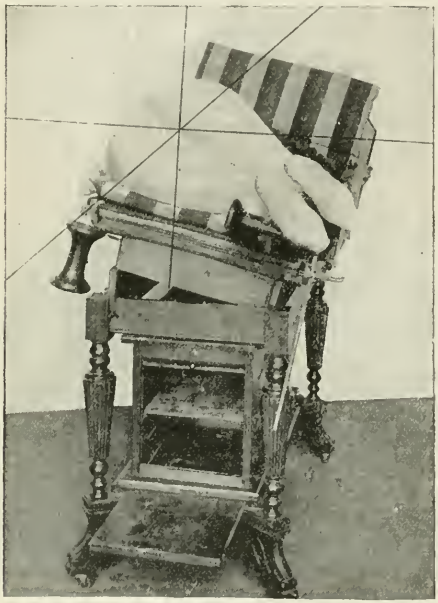

FIG. I.

3. The holding of the speculum, which requires the presence of a skilled assistant, the use of one hand of the operator, or a self-retaining instrument. The majority of physicians are not supplied with assistants, neither can they hold the speculum and at the same time comfortably and satisfactorily apply treatment.

To popularize and bring into general use the Sims speculum, a self-retaining attachment, simple in construction, readily applied and effective, is essential. A new holder is described and illustrated in the following paragraphs and Figs. II. and III.

The various parts of the speculum and holder, as shown in Fig. II., are designated by numbers for convenience of description: 1 is a Sims blade; 2 is a thumb-screw for setting this blade at various angles; 3 is a ratchet or notched lever, and attached by a joint to the blade; 4 is a sleeve for receiving the lever; 5 is a spring catch; 6 is a double spring lever; 7 is the cross-bar.

The blade is first introduced and turned up against the perineum. The double lever is placed over the sacrum with its projecting end under the outside clothing, or over it, as is most convenient, and the cross-bar rests upon the round of the buttocks, which become the fulcrum. The lever (3) is then introduced into the sleeve, and traction is made upon the blade by the finger pressing upon the thumb-screw (Fig. II.), and the thumb pressing upon the end of the upper spring under the catch; thus the two parts of the double spring are approximated sufficiently to produce the desired degree of tension. The ratchet catches and holds the lever wherever set. The double lever rests upon the back over and above the sacrum, the cross-bar being supported by the round of the buttocks. The instrument is removed by freeing the lever (3), either by pressing open the spring (5) or turning the double lever to either side.

FIG. II.[1]

Fig. III. illustrates the same appliance for holding the speculum, except that there is attached to the Sims blade the Thomas depressor. With the patient postured in the lateral position upon a horizontal plane a depressor is essential. If the patient be postured in the knee-thigh-chest or exaggerated Sims position, the depressor is not required. This mechanism is applied with facility, and does its work perfectly.

With this speculum and the patient postured in the knee-thigh-chest position, inspection and treatment are executed with facility, ease, and comfort, and the operator will have no desire to return to the usual methods in vogue for intra-vaginal treatment and ocular examination.

Dr. Charles P. Noble says that "Gynecologists must impress the general practitioner with the fact that the diseases of women are largely preventable, and make him feel his responsibility both as to their production after the present methods of practice, and as to the possibilities of their prevention after improved methods.

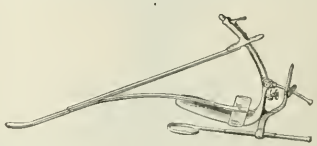

FIG. III.

"When the family physician realizes that it lies within his power very largely to prevent disease among women of the families committed to his care, his sense of moral obligation will spur him on to do his full duty in this matter. When that day comes the universal prevalence of disease among women will cease to be a reproach to preventive medicine."

258 FRANKLIN STREET.

Hippuric Acid as a Diuretic.—This acid, obtained from the urine of the cow, is a favorite diuretic with many French practitioners. Dujardin-Beaumetz prescribes it combined with lime.

Hippuric acid	25 grammes.
Milk of lime sufficient to neutralize it.	
Simple syrup	500 grammes.
Essence of lemon to flavor.	

Four to six tablespoonfuls daily. As before mentioned it is excreted in the urine as benzoic acid.—*Provincial Medical Journal.*

[1] Patent applied for.

Leprosy	0	0

The Duty of the State to the Insane.—In the October number of the *Popular Science Monthly*, Dr. Andrew McFarlane, of Albany, defines this to be as follows: 1. Separate treatment of the curable and incurable under one medical executive. 2. For the curable, true hospital treatment, with all the medical skill, nursing, and care, regardless of expense, which the character of the case demands. 3. Simple, humane, custodial care at moderate expense, for the incurable.

In a brief historical review of the care of the insane by this State since 1843, he shows that the principle of separate treatment of the curable and incurable had always been observed, until recent legislation, commendable as it is in other respects, has directed that all the insane of a given district be grouped together in one institution. A remnant of the principle remains in the provision for a larger allowance for care during the first three years after commitment, this being $4.25 per week, against $2.50 per week after that period. He believes, however, that the interests of the recent and curable cases will suffer from the influx of so many incurables who have until now been confined in county institutions. He thinks the time ripe, therefore, for the establishment of an annex to each State hospital, which shall be conducted on the same plan as a general hospital, in which vigorous measures shall be adopted for the cure of all promising cases. He regards this as a better plan than the establishment of entirely separate hospitals for this purpose, or than pavilions or wards attached to general hospitals. Special medical skill, experienced nurses, and means of mental diversion and occupation, such as are required in many cases, are already to be found at the State hospitals, while they could hardly be obtained elsewhere, unless perhaps in the very largest centres, where alone specialists on mental diseases are to be found.

The advantages to patients, nurses, and physicians in the State hospitals would, he believes, be very great. The physicians are, under the plan of management now in vogue, handicapped by many extraneous duties. Each has over two hundred patients under his care, and has to provide means for their entertainment and employment, besides recording clinical histories, and attending to correspondence and visitors. The benefit to the patients to be derived from the removal of those who have become recently insane from the chronic cases is apparent. The derisive remarks of the latter, their delusions, and their offensive words and actions, frequently aggravate the condition of the new-comer, adding dread or horror to his melancholy, or strengthening his delusions and morbid fancies. In a State hospital containing a thousand patients, there are now a medical superintendent, five assistant physicians, and a woman physician. Not more than a hundred, and probably only sixty, of the patients are curable. The remainder require kind custodial care only, and two or three physicians would ordinarily be sufficient for their needs. The other physicians could thus be left free to devote themselves to the recent and curable cases, who should be placed in small home-like cottages, containing a separate room for each patient, and provided with every facility for active treatment. Rigid physical examinations should be made, including investigation of the blood and excretions, and the use of the sphygmograph and ophthalmoscope; and baths of all kinds, massage, and electricity should be included in the treatment available. Under such circumstances, a hope of increasing our knowledge of the nature and best means of treatment of insanity might be reasonably cherished. The nurses for these cases should not be limited in number. They should be selected from the best of those already employed in the institution, and should have associated with them several nurses trained in general hospitals. This association and the importance of the work assigned to them would arouse a better spirit among the nurses in hospitals for the insane. He believes also that the medical spirit would be more likely to be kept up by the physicians in those hospitals. He quotes in support of this proposition from the transactions of the British Medico-psychological Society, in reference to the best method of keeping up the medical spirit in asylums for the insane. The following conditions were regarded as essential: 1. Classification—the curable from the incurable. 2. Hospital treatment for the curable. 3. Trained attendants. 4. More physicians and a rearrangement of duties.

He regards the paying of $4.25 per week for the first three years of a patient's stay in the hospital, and $2.50 afterward as a double injustice. The cases unmistakably incurable on admission, of whom there are many, do not require any unusual care, and the curable cases do not receive it, in spite of the extra allowance, because no special provision is allowed by the plan of management of the hospitals. The only result from the arrangement, then, is to raise the general standard of care. He urges that economy is best observed by making every effort to cure all promising cases. These come as a rule from the strong, productive classes, and are temporarily overcome by the effect of ill-health, trouble, care, or overwork; the incurable cases, on the other hand, are often mental incapables to start with, the victims of degeneracy in their ancestors. The average duration of life of such an incurable is twelve years, and the cost of his maintenance about $5,000. To prevent as many as possible from lapsing into incurability becomes therefore true economy. The cost of maintenance for each curable patient under the plan he suggests, would, he believes, be not more than $10 a week. If eighty patients, in a hospital containing a thousand, required this treatment, and the remainder cost each $3 weekly, the total weekly cost would be $3,560. At present the average weekly cost per patient is $3.50, or $3,500 per thousand. In conclusion, he urges that the plan is already in successful operation in Heidelberg and Strasburg, and is contemplated in Scotland.

Life Insurance Medical Recommendations.—A life insurance company is a sponge. It belongs to the octopeda or millepeda. It has a head-centre, grasping arms which extend to immense distances, agents as suckers and medicine men as tentacles or feelers. Through its agents it sucks into its colonial meshes such an enormous surplus of nutriment, that it permits its chief sucker to retain fifty per cent. of the premium blood drawn from the veins of each newly captured victim; while its corpulent head-centre appropriates an amount of this same vital fluid which, if transmuted into coin, would equal from ten thousand to seventy thousand ducats annually. The tentacles decide as to the sanitary condition of the victims. They receive scanty pabulum for their services, which are, or should be, of the greatest value. The judgment of other medical men (especially those of recognized prominence) as to the ability and fitness of the tentacles is constantly sought by the head-centre. The opinion desired may be of immense importance; it may insure success or ward off disaster; but the insurance octopus sponges the

opinion; he disgorges no ducats; he emits not even a worthless thank. He propounds in a circular a series of questions as to the age of the tentacle whom he proposes to employ, when and where he was educated, his qualifications as a diagnostician, the acuteness of his senses, especially his hearing, the amount of his business, his shrewdness, his mental and moral integrity, his ability to resist the allurements of the willing victims and the anxious sucker, his social and professional standing; and then he craftily pretends that the valuable time spent in answering fully these, and many more searching questions, is for the sole benefit of the proposed tentacle, while at every moment he knows that the pretence is a false one, and employed only to excuse sponging the wished-for information from the meek and complaisant physician. More than this. He is guilty of the contemptible meanness of promising that if the friendly tentacle shall be maligned and betrayed, the gratuitous betrayal will be guarded sacredly as "confidential."—H. D. Didama, M.D., "Transactions of the New York State Medical Association," vol. 1892.

Startling Effect of Animal Extracts.—Professor Solomon Muhlbach reports the following case (*Medico-Financial World*). J. L. S——, aged twenty-two when first treated in 1878. A native of Boston. This young man was a slender, consumptive-looking fellow, whose three brothers, an uncle, and aunt had died of phthisis. He was a close student, devoting his whole attention to literary pursuits. His muscular development was much below the normal. He had an annoying cough, had lost twenty pounds in weight during the preceding six months, and was troubled with night-sweats; no hemorrhages. Being convinced that this young man was a victim of that dread disease, the "white dead" of our modern times, consumption, I immediately began treating him with my (at that time) new extract of hogs' lungs, to which I had given the name pneumonine porca. This I injected subcutaneously, in proper dosage, so many times daily as his condition required. There was a marked and rapid improvement in the condition of his lungs. Cough became much less frequent, expectoration decreased, night sweats ceased. I now began to give him bicepine ursa horribilis in proper dosage, and was extremely gratified to note immediate increase in his muscular development. Coincident with this improvement there came an unexpected and astounding moral change in this young man. He developed marked hoggish and bearish traits of character! One day, entering my laboratory without permission, he drank off at one gulp a large percolator full of mixed extracts of all the organs of the bear. I was horrified, expecting a fatal result, but to my surprise he only expressed gratification and pleasure at having gotten such "good soup." The changes that henceforth ensued in the physical, mental, and moral constituency of this unfortunate young man, consequent upon his ingestion of the animal extracts of the hog and the bear, were rapid and lamentable. He forsook his literary pursuits and became a sport, finally drifting into the prize-ring, where he soon attained a most deplorable popularity and success. The prolonged effects of this medication in 1878 are somewhat remarkable, for it was not until 1890 that the action on the physiological remedies began to wear off, and only in 1892 did he renew his literary labors, so suddenly terminated fourteen years before. It is especially noteworthy that his bicipital circumference, which was $8\frac{3}{4}$ inches before treatment, increased to $19\frac{3}{8}$ after treatment. The hint given me by the moral changes noted in the preceding patient was not lost.

Chlorate of Soda in Cancer of the Stomach.—At a meeting of the French Association for the Advancement of Science, in August last, Dr. Brissaud, of Paris, made a report upon the above subject. He said that it was an established fact that solutions of chlorate of potash exert a very favorable influence on epithelioma of the mouth and certain forms of cancroid of the face. The successful results obtained with this method induced him to try the effect of the corresponding salt of sodium in the treatment of carcinoma of the stomach. This salt was selected because it is much less toxic and more soluble than chlorate of potash, seeing that relatively large doses may be injected into animals without ill effect, and that it is soluble in three times its own weight of water, while the potassium salt requires twenty parts of water for complete solution. He had treated several undoubted cases of cancer of the stomach by the administration of chlorate of sodium in doses varying from eight to sixteen grammes (two to four drachms) in the twenty-four hours. The results were so satisfactory that if his observations were limited to one or two cases only he would hesitate to publish them, because he might possibly have mistaken cases of chronic gastritis for cancer; for the former, as is well known, sometimes present all the symptoms of malignant disease. But during the last four years he had tried this treatment with equal success in five successive cases of localized gastric cancer, and it is difficult to admit that an error of diagnosis was committed in each of these five cases; this is the more improbable seeing that three of the patients presented a distinct epigastric tumor. In every case the treatment was followed by the most remarkable improvement, amounting practically to a cure. The drug was given in doses of twelve, fourteen, or even sixteen grammes in the twenty-four hours, and the patients may now be regarded as radically cured. Under the influence of this treatment, the melæna, hæmatemesis, and cachexia disappeared; the appetite returned; and in the three cases in which a tumor could be detected in the epigastrium, it gradually subsided until no trace of it was left at the end of six weeks. On the other hand, the treatment failed in a number of cases, for while chlorate of sodium seems to exert a favorable influence on malignant tumors of the epithelial type, it produces no effect whatever on the interstitial sarcomatous type of neoplasms. Moreover, the failure in some of these cases is to be attributed either to the fact that cancer had already spread to other organs, or to the presence of complications which were not amenable to the treatment. For example, in one case the liver was already involved when the administration of chlorate of soda was commenced. In another patient, a young woman who had at first experienced some relief from the treatment, the disease suddenly extended to other parts of the body, where it developed with extreme rapidity. She was a patient of Dr. Nélaton; she received sixteen grammes of chlorate of soda a day, and in the course of a few weeks hæmatemesis ceased, appetite returned, and she put on sixteen pounds in weight. This improvement was so remarkable as to suggest an error of diagnosis. At the autopsy, however, cancerous nodules were found in various organs and tissues. In a third case death was due to phlebitis of the inferior vena cava. It cannot, therefore, be included in the statistics of the treatment of gastric cancer by chlorate of soda.

The Creation of God.—Dr. Jacob Hartmann, of St. Louis Medical College, has written a treatise in explanation of the above subject. His theory of the origin of life is marvellously simple and axiomatic: "Vegetable chemical compounds, organic substances, can be produced only under certain vitalizing conditions and influences." "Wherever upon the surface of this earth the sun's rays produce a certain degree of heat, temperature, CHO may combine and evolve vegetable life." It seems hard to realize that this explanation has never occurred to Tyndall, Bastian, Sanderson, and others of the non-illuminati. Dr. Hartmann has also an explanation of the origin of mind and the breath, which he puts poetically thus:

> "No soul you will ever find,
> Trust not in its life or death;
> Education makes the mind;
> Oxygen is the life's breath."

The creation of God is a mighty mystery, but hardly so great a one as that of the creation of the author.

DERMATOLOGY IN ITS PRACTICAL RELATIONS TO GENERAL MEDICINE.[1]

BY H. RADCLIFFE CROCKER, M.D., F.R.C.P. LOND.,

PHYSICIAN FOR DISEASES OF THE SKIN TO UNIVERSITY COLLEGE HOSPITAL, LONDON.

WHILE no one doubts the advantage of a sound knowledge of general medicine as a preliminary to the study of any special branch of it, we are apt to overlook the advantage to general medicine that may accrue from the careful study of a special organ and its diseases. In selecting a subject on which to address you, it seemed to me probable that as the subject must necessarily be dermatological, its treatment from as broad a stand-point as possible would be most congenial on an occasion like this to you and to myself. I have tried to place myself in the position of what, in England, we call a general practitioner, and to answer the question, How will a knowledge of diseases which affect the skin be of advantage in the diagnosis, the prognosis, or the treatment of many diseases of other organs?

I pass by its advantages as a training in close observation, although in this direction it is of high value, nor shall I dwell upon the opportunities it presents for studying pathological processes as they go on during life, which in disease of other organs we have to infer from what we see upon the post-mortem table. One thing I would seek to impress upon you, the practical value of your knowledge is in proportion to its accuracy. This, however, dermatology shares with the other branches of medicine; nothing is more fallacious and more disappointing, when you are face to face with a case which is not cut exactly upon a text book pattern, than what is called "a general knowledge of the subject."

You can come to no sound decision unless you are aware in what respects the disease in question may depart from the usual type, and you are driven to the last resort of the destitute diagnostician, viz., to treat the most prominent or most disagreeable symptoms. In studying our subject I propose to take up each organ and discuss what diseases of the skin are found in relation to it, laying stress only upon those which are either characteristic of the disease, or are at least so frequently associated with it as to immediately suggest whether the particular disease may be present.

I shall pass lightly by those diseases of the skin which only own an etiological relationship of so occasional a character as to render it doubtful whether in any particular case such relationship exists at all, and commence with the kidney because its functional relation to that of the skin is so close in health, as well as in disease, that it is only surprising that renal and skin disorders do not depend even more closely on each other than clinical facts would warrant us in asserting.

Several eruptions play an important part in relation to diseases of the kidney and urinary disorders. The most familiar of these are boils and carbuncles. Although these lesions are directly due to the presence of the micro-organisms staphylococcus aureus and albus, as is well known, they find an extremely congenial soil in persons suffering from diabetes mellitus, and if a patient comes to you with boils or carbuncles it would be culpable neglect not to examine the urine whatever the patient might complain of. Even if there is no sugar in the urine they should suggest an inquiry as to external causes, and there is no more prolific source of boils, carbuncles, and abscesses than sewer-gas poisoning; the drains and water supply, therefore, should engage your attention. Eczema and pruritus of the genitalia are also frequent and familiar concomitants of diabetes; urticarial and erythematous eruptions are not uncommon but less significant; but there is one affection which, although rare, is of considerable importance because it occurs in persons whom you would not *primâ facie* suspect of glycosuria while a knowledge of this eruption would at once put you on the track. Let me give you a case in point:

A gentleman, aged thirty-eight, was sent to me for the diagnosis of an eruption which had appeared on the buttocks two months before I saw him, and soon after came out on the front of the arm, and then on the elbows and knees, and the lesions had gradually increased in number. The eruption consisted of papules, from a hemp-seed to a pea in size, with a red base and yellow apex, and there were no subjective symptoms; the patient looked well and complained of nothing, only when questioned he admitted some lassitude and that he was more easily tired during the last nine months than he had been formerly. Recognizing that the eruption was that known as exanthema diabeticorum, I at once examined the urine and found sugar, which subsequently was shown to amount to eighteen grains to the ounce, while he passed about seventy ounces of urine per diem. With suitable dietary and other treatment the sugar and the eruption both disappeared. I emphasize this case because it is a very good illustration of the service of dermatology to general medicine. The practitioner who sent the patient to me was a well-trained man, not at all likely to overlook a case of diabetes in which other symptoms besides the eruption pointed to glycosuria.

A generalized ache, such as this case of folliculitis of which I show you the drawing, deserves a passing mention in connection with diabetes; but what may be called terminal gangrene, the gangrene of fingers, toes, or penis, or superficial patches on the limbs, is not of so much practical importance from the point of view of diagnosis, as it only occurs quite late in the disease, when the merest tyro would not miss the cause of it. Skin eruptions play a less important part in relation to albuminuria. Urticaria, the ubiquitous eczema, and occasionally general pruritus, no doubt occur sometimes in granular kidney, and other forms of chronic Bright's disease, but are not specially significant of renal inadequacy except perhaps in old people. A very important erythema, however, sometimes occurs in advanced chronic Bright's disease, which is of grave prognostic significance, as it is a uræmic phenomenon and marks therefore the beginning of the end. This uræmic erythema may at first resemble measles or scarlatina, or be in small or large uniform separate patches, but coalescence of the initial lesions soon occurs and the diffuse redness or superficial dermatitis spreads rapidly over the body and not infrequently becomes universal, and is soon followed by desquamation in large flakes of the whole surface, while occasionally vesicles and pustules may develop.

The following is a good example: An apparently well-preserved man, aged eighty, who looked ten years younger, had suffered from eczema off and on for several months. When I saw him the eruption occupied the greater part of the lower limbs and the ears. There was a faint trace of albumin in the urine, but only what would be

[1] An address delivered at Chicago.

found in many men of his age, and his organs appeared otherwise sound. The eczema improved under treatment, but he had been in the habit of taking bromide and chloral for sleeplessness, which I had not been able to stop altogether, and one night the nurse gave him a second dose. No immediate ill effects were shown, but from that time he gradually got weaker, and about a month after I first saw him a deep red erythema appeared in patches on the trunk, and rapidly spread over the whole body surface, speedily followed by copious desquamation everywhere except where the eczema was enveloped with Lassar's paste. After this he went steadily down hill, became weaker daily, then his mind wandered, and he died comatose about a month after the uræmic erythema first appeared.

Another instance came quite recently under my notice, in a medical friend who had had albuminuria after scarlet fever for nearly forty years. He had had uræmic symptoms two years before, but the fatal event had been averted, and he had apparently quite recovered. Then with that unwise self-medication which characterizes our tribe he put himself on a milk diet, and in a few days became completely prostrated. He partially rallied with good feeding up, and went about for a few weeks, then a flat, papular eruption appeared on the back of the hands and on the hips, which after about a week began to generalize, and when I saw him the whole trunk and lower limbs were covered with measle-like papules, which at the wrists had enlarged to flat, slightly raised patches one-half an inch in diameter, while on the back of the hands they had coalesced into a diffuse scaly area occupying the whole hand. The eruption had itched when it first appeared, but this had ceased when I saw him.

The liver is an organ which seems to have been created as a refuge for our weaker brethren. If the doctor can but tell the patient with any show of plausibility that his liver is out of order, both are at once made content, the doctor because he has been able to give an answer which satisfies the mind of the patient, while the latter has a label for his disease which he thinks he understands, and which probably jumps with his preconceived ideas.

Apart from diabetes and the cutaneous lesions associated with it which we have already considered, the liver is not directly responsible for many skin troubles. One of the most persistent is general pruritus. In any case of pruritus not due to an inflammatory eruption, after excluding parasitic irritation, the liver is one of the first organs requiring investigation as to its physical conformation, and the way in which it is carrying on its functions.

That condition which Murchison described under the title of "lithæmia," is one of the commonest causes of severe and often very persistent pruritus, sometimes without any cutaneous lesion other than may be produced by scratching, at others with concomitant or antecedent urticaria. During, and after jaundice also, pruritus is sometimes a very persistent and very distressing symptom.

Another affection associated with long standing jaundice is xanthoma multiplex. It is immaterial what the cause of the jaundice may be—gall-stone, carcinoma, or stricture of the common duct—long-standing jaundice is likely to be accompanied by xanthoma multiplex. I emphasize the term "multiplex" because xanthoma of the eyelids alone is more frequently associated with migraine than with any other disease, and may be quite independent of recognizable hepatic derangement. On the other hand, probably ninety-five per cent. of xanthoma multiplex in adults own jaundice as an antecedent, and although it may occasionally occur without jaundice in every such case, the most careful investigation into the liver should at once be made; for in some few instances the xanthoma anticipates the jaundice instead of following it. Such was the case of the patient of which I show you the drawings. For years she had xanthoma without any alteration of the complexion except a sallowness, but about twelve months before her death she became deeply jaundiced, and died of biliary cirrhosis. She had, however, been a martyr to migraine all her life, and as usual the xanthoma was at first limited to her eyelids, and appeared on the limbs several years later.

"Liver spots" refer to the color, and not to any etiological relationship to the liver.

Pigmentation, especially when diffuse or in large patches, plays an important part in many general diseases. The well-known bronzing of Addison's disease is, as you are well aware, in most cases its most prominent symptom; it is general in its distribution, but is most strongly marked in the face, neck, hands, axillæ, umbilicus, and genital region; it affects the upper part of the body before the lower, as a rule, and involves the mucous membranes to a greater or less degree. It may be only slight throughout, or gradually increase till the skin is as dark as that of a negro, and in rare instances only, is it absent.

In Graves's disease, or exophthalmic goitre, pigmentation is a very frequent symptom, sometimes only as freckles, especially about the orbits, or there may be local or general bronzing, or it may take the form of leucoderma. The so-called uterine chloasma in connection with pregnancy or uterine derangements is common enough, but it may occasionally occur in other abdominal conditions, such as abdominal tuberculosis, cirrhosis of liver, and I have seen it in connection with chronic constipation; and on the successful treatment of this condition it disappeared. Although usually confined to the face and neck, it may also affect the trunk and limbs, and in one instance the patient was spotted like a leopard.

In all the above conditions, it is doubtless in direct connection with disturbance of the abdominal sympathetic, especially the semilunar ganglia.

In malaria also, the skin may become yellowish, yellowish-brown, or even black, as in the "Black Disease" of Assam, where it is acute in development, but in the majority of cases it is only produced after prolonged exposure to malarial influences, and is due to destruction of blood-corpuscles, and the circulation of pigment particles.

The diffuse bronzing of leprosy need only be mentioned.

Pigment patches sometimes occur with rheumatoid arthritis, and as one of the symptoms of senile degeneration of the skin.

The yellowness of jaundice I need not dwell upon, but pigmentation in connection with the prolonged administration of certain drugs is worthy of your attention. Years ago, when nitrate of silver was considered to be the best treatment for epilepsy, blue- or slate-colored persons were met with much more frequently than they are now, since nitrate of silver has been supplanted by bromide; but argyria, as it is called, may also occur from its topical application, and in not a few cases has it arisen from a solution of it having been employed to paint the fauces and pharynx.

There is a strong reason to suppose that the man whose portrait is shown acquired the discoloration in this way, and that, too, though the solution was used many years before the blue color developed. I ascertained, with almost certainty, that he had not taken or used nitrate of silver for nearly thirty years, and that the pigmentation was comparatively recent, he adduced the conclusive evidence that he had only been married to a young second wife for four years, and "if I had been blue," said he, "she would not have married me."

But if bromide of potassium has saved a good many epileptics from being turned blue, it has indirectly been the means of turning many such brown, and in this way: In order to control the so-called bromide acne, Fowler's solution is often combined with the bromide mixture, and this being taken for months, or even years, arsenical pigmentation results; not a few such cases having been referred to me for diagnosis by the very neurologists under whose auspices they have taken the drug.

The same accident frequently occurs in children with chorea, to whom arsenic is often given.

Arsenical pigmentation may be recognized, partly by its sepia tint, and on the trunk in the early stage the hair-follicles are the last part affected; hence there are white dots on a dark sepia-brown ground, but at a later stage these also are involved, and then the tint is uniform.

The border shades off gradually into the normal skin, and the face, neck, and abdomen are generally most deeply tinted. When psoriasis has been treated by arsenic, the site of the old patches is the seat of the pigment, but if given for a very long period diffuse pigmentation may ensue. As a rule, however, it is not in the treatment of skin diseases, but in those of the nervous system, such as epilepsy and chorea, that diffuse arsenical pigmentation is produced. The main factors in its production are the dose and the length of administration, but idiosyncrasy also plays a part, as a very moderate quantity will sometimes produce it, and children are much more susceptible to its influence in this respect. In one case, a girl, with chorea, to whom I gave three minims of Fowler's solution, gradually increased to five minims three times a day, it developed within a fortnight. Arsenic also produces hyperidrosis of the palms and soles, and horny thickening, beginning round the sweat orifices, and gradually forming a uniform horny plate over the whole palmar, and all but the arch of the plantar surface. Finally, it predisposes, if it does not actually produce, herpes zoster sufficiently often to show that there is an etiological relationship.

The practitioner should be aware of the possibility and appearance of eruptions produced by the administration of certain drugs. As a rule, drugs cause eruptions of an erythematous, urticarial, and occasionally vesicular or bullous character, not at all distinctive, and the origin can only be suspected when the patient is known to have been taking a drug which may occasionally produce eruptions of that character. The copaiba erythema is perhaps the most familiar example, but its characters are very variable.

Two classes of drugs only, besides those mentioned already, produce distinctive rashes, viz., bromides and iodides. They are often, however, very like each other, but can usually be distinguished pretty readily, and they are distinct from any other kind of eruption. Briefly stated, the bromide rash consists of an aggregation of pin's-head pustules on a raised, soft, red plateau of an inflammatory tissue. The iodide eruption has a bullous appearance, instead of a purulent character, and is not so distinctly made up of an aggregation of smaller lesions. I said "of a bullous appearance," because, as a matter of fact, the lesions are solid in spite of their vesicular aspect, and on pricking them only a tiny drop of clear fluid escapes. Both these eruptions occur much more frequently in children than in adults, and in infants very small doses, *e.g.*, the quantity derived from the mother's milk when she is taking bromide or iodide of potassium, has produced it in some instances.

In adults, however, the matter stands on a somewhat different footing, and unless the patient has had large doses, or the drug has been given for a long time, an iodide or bromide eruption produced by moderate doses is indicative of defective elimination due to disease of either the heart or the kidney. I remember a case which I was asked to see in a small-pox hospital. The patient, a middle-aged woman, had been sent in as a case of small-pox, and the authorities, though well aware that it was not small-pox, were puzzled as to its nature. It was a very well-marked case, and I easily recognized that it was a bullous iodide eruption, and moreover predicted that she had either cardiac or renal trouble. This was correct, for she had albuminuria and mitral regurgitation, and she had only taken a few five-grain doses of iodide of potassium. The patient depicted in the drawing had also only had a few small doses, and suffered from the large white kidney. That the rash is distinctive this photograph shows. It was sent to me for a diagnosis by a practitioner who had a dispensary for diseases of the skin in a provincial town. The history was that it had come out in the course of a few days, that the lesions had a vesicular appearance, but were solid, and that the eruption had been out about a fortnight. I wrote that it was an iodide eruption; the reply was, "that it was impossible, as the man had had no iodide of potassium." I said that I knew of no other eruption with such characters, and told the doctor to inquire if the patient had taken any quack medicine, especially "Clark's Blood Mixture," which is well known to contain iodide of potassium. It was only after much cross-examination that the patient admitted that he had taken "Clark's Blood Mixture," and afterward half a dozen empty bottles were found to corroborate his admission, his first contradictions having been due to forgetfulness, not lack of *bona fide*, and the rash, as frequently happens, not having appeared until more than a week after he had left off the medicine, the cause and effect were not connected in his alcoholic muddled brain, for the man was a drinker with a weak heart and diseased kidneys.

I have related this case to show you that the diagnosis can be made in a well-marked case quite independently of history, and even in the face of *prima facie* evidence to the contrary.

Other forms of eruption may also be produced by both bromides and iodides, but they are not distinctive, and require evidence of the antecedent drug to enable a certain diagnosis to be made, though there is strong ground for suspecting the iodides when large patches of induration with bright color are seen scattered about the body.

Although the condition of the alimentary canal has an important influence on the production, continuance, and course of many cutaneous eruptions, chiefly of the urticarial, erythematous, or eczematous classes, there is nothing distinctive about the eruptions so produced, and they may be equally well due to other causes for aught we can tell from the skin lesions themselves. True it is that urticaria, both in adults and children, is more frequently due to disorders of the alimentary canal than from all other causes put together, and naturally, therefore, we seek first for its cause in such disorders; but urticaria from chill, for instance, is indistinguishable from urticaria ab ingesta, and it is only by investigation into the history of onset and the present conditions of the digestive organs, that we can form an opinion as to its cause. In the urticaria of children, however, although external parasites will sometimes be the exciting cause, in nearly all cases gastro-intestinal catarrh is the real factor to be dealt with, and a rigid dietary, forbidding all sugar and starch food, except with maltine, is a prime necessity, while alkalies, bismuth, and a protection against chills are the other indications.

There is, however, one disease in men which is always due to dyspepsia, and in women nearly always so, viz., acne rosacea. I say nearly always so in women, because another factor may sometimes be the more important cause, viz., uterine disorder; but even then stomach derangement is a common concomitant. Acne rosacea is the result of chronic reflex hyperæmia of the face, the pimples being an epiphenomenon of the oft-repeated congestion. It may be produced without the patient suffering consciously from indigestion, the reflex flushing of the face after meals being sometimes the only tangible evidence that digestion is not normally performed. This applies only to the slighter cases; in the worst forms other symptoms are also prominent, and alcoholism and exposure to vicissitudes of weather play an important part in the highest development of the disease, of which I show you an instance. The patient was a cabman, who combined all the necessary factors, his occupation exposed him to the weather, while he admitted that he was "a thirsty soul" and drank when he wanted to, but the growth took a good start after being kicked by a horse. Such noses can be very satisfactorily trimmed down by the knife, though the result falls somewhat short of a "classical ideal."

There is another very rare affection called chromidrosis, in which obstinate chronic constipation is almost

always present. It consists of a colored sweat, or sebaceous secretion. When the sebaceous glands are concerned it is sometimes called seborrhœa nigricans, and chromidrosis is then reserved for the sweat affection. They are, however, evidently identical in origin and distribution, and may be treated as one affection, especially if Unna's views are correct. He follows Neisser and says, "The sweat coils secrete fat and the duct only water or sweat."

However this may be, clinically we see colored patches, usually black or sepia, especially in the seborrhœic cases. Sometimes in the sweat cases there may be blue from azure to indigo, and red, green, yellow, and violet sweats have been recorded, and even a change of tint, blue to black, yellow to black, and blue to ochre have been observed. The theory put forward to explain it is, that indigo is formed from indican derived from the absorption of indol from the long-retained fæces and subsequent oxidation. However this may be, free purgation and enemata to get rid of the accumulation is the best treatment to pursue.

Do not, however, run away with the idea that every young woman with black under her eyes is suffering from chromidrosis. The condition is so easily simulated that hysterical women not infrequently produce it artificially. Such women generally have some increase of pigmentation of the eyelids which suggests accentuation to their morbidly perverted minds longing for sympathy or attention, analogous to what is seen in conceited men of small ability, who when they fail to become celebrated are glad to become notorious. Such women generally have some natural increase of pigment of the eyelids, which suggests accentuation.

It may be expected that I should have much to say on the relation of diseases of the skin to the nervous system, but it is not so. It is true that herpes zoster is always the result of inflammation of some part of a nerve or nerves, especially of the posterior ganglion of the main nerve domain affected; that herpes febrilis is the cutaneous expression of an antecedent rigor, or at least chilliness; that multiple anæsthetic whitlows are indicative of Morran's disease; that bullæ are very likely to appear in the domain of a nerve affected with inflammation; and that the thinned, slightly reddened, and shining appearance known as "glossy skin" is also the result of a neuritis, whether gouty, rheumatic, or traumatic; but those nerve conditions may be present and no corresponding cutaneous lesions appear. It is true, also, that many cutaneous lesions have arisen from nervous shocks, such as sudden and great grief, fear, etc. Among such consequences general alopecia, often with loss of nails, sudden blanching of the hair, severe attacks of eczema, pityriasis rubra, lichen planus, and psoriasis, but there is nothing in the cutaneous lesion itself to suggest its origin, which is only discovered by the history furnished by the patient.

Many years ago I made careful investigation into the etiological relationship of nerve lesions to skin diseases, and the conclusions I arrived at were, that while the nervous system may determine the occurrence, distribution, extent, and intensity, it has no influence on the kind of eruption; and further, that less serious consequences ensue from cutting off the nervous supply than from irritation or inflammatory lesions of the parts of the nervous system that affect the skin; that the kind of eruption produced by the nervous system varies greatly, often without any evident reason, when the nervous defect is apparently the same in place and kind; that the same kind of nervous lesion that at one time appears to excite an eruption or other nutritive defect in the skin, even more frequently produces no change in the skin whatever. In short, the nervous influence is an indirect one. Conversely, therefore, we cannot expect skin lesions to afford much assistance in the diagnosis or treatment of nerve lesions. Recently, however, F. Head, by studying the distribution of a large number of cases of zoster, has been greatly assisted in mapping out the areas of skin affected in connection with visceral pain. And some forms of erythema, chiefly patchy or diffuse, are to be met with in peripheral neuritis such as we see in pellagra, acrodynia, and beriberi.

Hitherto we have discussed skin diseases in relation to diseases of the other organs. I pass on now to their connection with diathetic conditions. I need not dwell upon such diseases as syphilis and leprosy, where the skin lesions are so prominent that they are considered to be a branch of dermatology; the erythema connected with pellagra and acrodynia and beriberi, though of neuropathological importance, is also scarcely more than of academic interest to you. The eruption of erythema nodosum may and should suggest an inquiry for a rheumatic taint, for rheumatic symptoms such as arthritis, sour sweats, sore throats, and even endocarditis, have been found associated with this eruption so frequently, that even when the skin lesions are present alone, the suspicion of rheumatism should be excited. Other forms of erythema multiforme have been supposed to be connected with rheumatism, but the evidence is less definite. One purpuric form, however, is so constantly associated with arthritic pains as to be called purpura or peliosis rheumatica, but it is not certain that the pains are really rheumatic. This eruption is really a hemorrhagic erythema, and this and another form of hemorrhagic erythema is also often associated with internal hemorrhages from the stomach, intestines, or the kidneys, as in the following case:

The patient, Samuel H——, aged thirty, was an omnibus driver, with a good family and personal history, except that for the last fifteen years he had noticed at times a red eruption on his arms and legs, with stiffness of the joints, which went off if he got warm. This attack began on December 30, 1888, the rash came out on the arms and legs without itching, but attended with the usual stiffness of the joints. On January 3d, diarrhœa supervened, and increased until the 12th, when vomiting of greenish-yellow fluid and blood was added. Next his stools were mixed with blood, and he became worse daily, and on January 21st he was admitted into University College Hospital, under my colleague, Dr. Poore. The next day purple spots came out on the left buttock and over the knees and elbows. The eruption was in papules, from a pin's head to a quarter of an inch in diameter, and did not itch, but was rather tender; he still passed blood by vomit and stool. In the next two days he was much better, but relapsed on the 25th, with great pain and diarrhœa; the stools were for the most part fluid, but with some scybala, were chiefly yellowish-gray, but contained blood, slime, and a jelly-like substance. The urine had a trace of albumin. He improved and went on well until February 8th, when he again relapsed severely, and the rash, which had faded, broke out again on both wrists and elbows, and was hemorrhagic as in the drawing. I saw him on the 9th, he was very prostrate, and I recommended five grains of quinine to be injected by the rectum; the next day he was better, but vomited occasionally, and the eruption was vesicular with increased hemorrhagic exudation. He had a slight relapse on the 14th and 15th, but after that progressed slowly but uninterruptedly; the rash only faded slowly. I believe that the explanation of this case is that it was due to ptomaïne poisoning, absorbed from retained scybala. During the attack the temperature varied from subnormal, even as low as 95° on one occasion, to 100.8° at its highest, but just over 100°F. was more common.

Here is a somewhat analogous case, in a girl aged thirteen. I saw her in her fourth annual attack at Christmas time, 1892. Each attack began with severe abdominal pains, vomiting and purging blood, very offensive breath, and hæmaturia. In the first and second attacks, which were the worst, besides the purpuric eruption on the limbs there were black blisters on the ears, and the eyes turned black. With recurrences the attacks lasted three to six weeks, but once as long as six months.

Another disease supposed to have a strong connection with gout is eczema. No doubt the two diseases often enough stand in etiological relationship to each other, but this relationship has been enormously exaggerated, so that, with the laity, eczema and gout have become almost synonymous terms, and anxious mothers bring their infants with eczema and ask "if it is gouty? as gout is in the family." I am bound to say that the profession are mainly responsible for this view, and many a puzzled practitioner, when asked the cause of an eczema, escapes from his dilemma by uttering, with solemn expression and tone, the mysterious words "suppressed gout." My advice to you is to continue to suppress it if you can. The tubercular is one of the most important diatheses, and it may be defined as an organization favorable to the growth of tubercle bacilli. There are certain skin affections which are generally acknowledged to be directly due to tubercle bacilli. There are others where the connection is only indirect.

Those directly due to tubercle bacilli are true or nodular lupus, scrofulous lupus, and its congeners scrofuloderma, lupus papillomatosus, lupus verrucosus, and its allies verruca necrogenica and tuberculosis verrucosa cutis; the last is the same affection as the post-mortem wart, but derived from animals instead of man; finally there is the acute tuberculous ulcer.

The last four are all examples of inoculation tubercle, though the acute tubercular ulcer is due to auto-inoculation, and the patient is always suffering from advanced phthisis.

In scrofulous lupus other evidences of scrofula are nearly always present, but in nodular lupus this is seldom the case, and it is more frequently the sole manifestation of an inheritance which is so fatal when the bacilli attack internal organs. In Europe, at all events, the proportion of cases in which phthisis is to be found in the family history of lupus patients is very large indeed. I qualified my statement by speaking only for Europe, because I am aware that my distinguished colleague, Dr. Nevins Hyde, from an analysis of eighteen cases came to a different conclusion, as only one had a history of phthisis in the family, and either America differs remarkably from Europe in this respect, or the number of cases being not large, it may have happened that Dr. Hyde had a run of cases with a good family history. That such runs do occur we all know, and a very remarkable one is Hebra's experience in another scrofulous affection to which I am about to allude, viz., lichen scrofulosorum. Hebra's first fifty cases were all males, and nearly all young adults; yet further experience has shown that the great bulk of cases occur in childhood, and that both sexes are about equally affected.

The lichen scrofulosorum, of which I have just spoken, is one of the eruptions only indirectly due to the tubercle bacillus. It is not an important eruption in itself, being little more than a hyperæmia of the lanugo follicles on the trunk and limbs, but it is very significant of the kind of patient with whom we have to deal. This knowledge comes in practically useful, not so much in extreme cases when keratitis, bone disease, and gland enlargement are very likely to be present, but in milder forms which are only brought under notice when, for instance, we are examining the chest of a child for pleurisy or other chest affection, and are perhaps puzzled to explain its presence.

Still another skin disease, usually seen in pronounced scrofulous patients, is acne scrofulosorum. It is a very rare affection, but its distribution on the buttocks and thighs is characteristic. Occasional pustules are frequently seen in lichen scrofulosorum, but in acne scrofulosorum, suppurative folliculitis with this distribution predominating, is the sole cutaneous lesion in addition to the malnutrition so frequent in such patients. A somewhat rare affection connected mainly, but not exclusively, with sebaceous glands, is that known as adenoma sebaceum. Its lesions are small, solid, vascular, millet-seed-sized nodules closely aggregated on the cheeks and chin, and along the naso-labial fold, and more sparsely on other parts of the face. They are doubtless of developmental origin, though they only show themselves in early childhood, and are intimately connected with similar nervous defects such as epilepsy, imbecility, or idiocy. Although this is not without exception in slight cases, it is true for the bad forms, and the affection is not rare in large asylums where cases with congenital mental defects are received.

Another disease with new-growths and poor mental development, is fibroma, or molluscum fibrosum, as it is sometimes called. The usual concomitants of such cases are stunted growth, coarse, ill-nourished, pigmented skins, and large pendulous growths in various parts of the body.

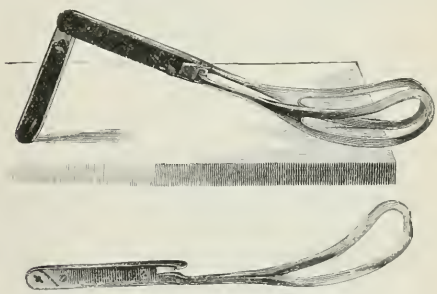
This rapid survey, which is all that the time at my disposal permits, by no means exhausts the subject, and there are many interesting and practical points which I should gladly have touched upon with regard to the exanthemata, in itself a large subject, the nails, the hair, and the several functions which afford useful indications to the thoughtful observer; but I must leave the discussion to another opportunity.

OPERATIVE INTERFERENCE DURING THE SECOND STAGE OF LABOR.

By T. J. McGILLICUDDY, A.M., M.D.,

OBSTETRIC SURGEON TO NEW YORK MOTHER'S HOME MATERNITY HOSPITAL.

Except in rare instances, such as cases of eclampsia, hemorrhage, or obstructions, there should be no operative interference during or before the first stage of labor. The duration of the second stage is exceedingly varied; in one patient it may last but a few moments, and in another, days, and it is generally toward its end that trouble arises. The theory that the bag of water is of no service



Figs. 1 and 2.—Author's Axis Traction Forceps.

after the cervix is dilated, and that the progress of labor is suspended until it is ruptured, either spontaneously or by the physician, seems to me to be erroneous. It has also a function in dilating the vagina, and, in some cases, even has the same effect on the perineum; to interfere with it, therefore, appears ordinarily like a meddlesome procedure. When the head is on the perineum, artificial rupture of the membranes, if they are still intact, seems sometimes to precipitate delivery, but even this is not always judicious.

The application of the forceps in a proper manner is something that requires the skill as well as all the care of a surgical operation. Every practitioner thinks he is competent to use the forceps, but to do it properly is quite another affair. Its skilful use does certainly decrease infantile mortality, but by its bungling manipulation it is increased.

There is no danger in ordinary delay at the inferior strait, but we should be careful that this does not become too protracted, and we must remember that each case should be treated on its own merits, as it will test the judgment and good sense of the attendant, by the

results attained. It makes no difference how long the woman is in labor, if she or the child is not in danger, and is not suffering excessively, there is no call for interference. The attendant should not consider his sacrifice of time, but should make his charges conditional, in case there is excessive waiting; neither will it do to be influenced in the application of the forceps by anything but the medical aspect of the case, as there is often a disposition to apply them sooner than is really necessary, urged by the apparent sufferings of the patient, and the importunities of relatives and friends to "do something

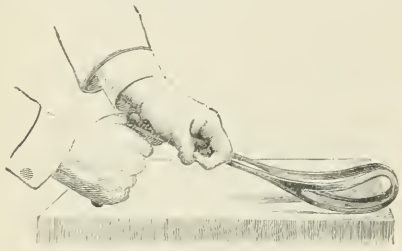


FIG. 3.—Method of Holding.

for her relief." Here we should not forget our anodynes and anæsthetics, but use morphia or chloroform as indicated. Some women suffer much longer than others, and, in their agitation and excitement, believing they will die undelivered, are often anxious for its application long before we are justified in using it. It is said that the forceps are applied far more frequently in private than in hospital practice, and that the policy of waiting on nature has with many given way to their earlier and more frequent use. This is to be deprecated, as in many in-

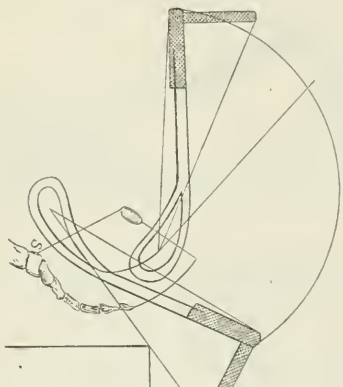

FIG. 4.—Line of Axis Traction and Mechanical Projection of Author's Traction Forceps.

stances, when they have been used at the superior strait with seeming success, the child often lives only a week or two and then dies, generally from some cerebro-spinal lesion.

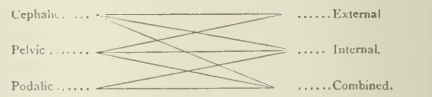
Manual or bandage pressure may often be employed in assisting the uterine contractions in expressing the fœtus. The hands should be spread out over the fundus, and firm, but not too severe, pressure, made during the pains according to Kristeller's method; or, if the patient is on the side, then a large roller towel or binder can be passed over the abdomen to be twisted behind into a knot and drawn tightly during each contraction, thus assisting the expulsion and gratifying the patient that something is being done to help her. This is much better than to stretch or to manipulate the perineum with the fingers, as many do. Then, if in spite of this assistance there is no progress, and the life of the child is prejudiced, as can be determined by watching the fœtal heart, and the integrity of the soft parts is endangered, we must apply the forceps.

There is no absolute rule to be laid down, but three per cent. would seem a fair average for interference; in the rest, if left to herself by non-interference, nature will gradually and safely finish the delivery. Meddlesome midwifery is as much to be deplored now as ever, and the patients often object to being "butchered," as they term it. Interference, even by the skilful, often means mischief; nature in all cases is the best judge, and performs her work beautifully. Even mild delirium is not, of itself alone, always an absolute indication for hastening the labor by instrumental interference, as some women become hysterically delirious upon slight provocation; but when pathological phenomena denoted by marked rise of temperature, weakness and rapidity of the mother's pulse, or feebleness and irregularity of the infant's, or when we think these threaten, there is no time for delay.

Episiotomy.—Episiotomy is a doubtful operation, and it is questionable if it does what it is intended for, as lacerations occur in spite of its performance. It is certainly one whose usefulness is very difficult to appreciate.

Perinorrhaphy.—Perineal tears of slight extent and where the muscles are not deeply involved, need not be sutured, as there is no special gaping and no loss of tissue; they generally unite immediately, if the knees are bandaged together. A laceration may, at first glance, appear serious, but it often subsides into a very small tear in a comparatively short time, and, in these cases, suturing is seldom imperative. The application of a stitch or two is simple enough, but the care thus taken by the obstetrician is seldom appreciated by the patient or her friends, and, if the tear is slight, it is better to leave its adjustment and repair to nature. Very severe or complete laceration should be always sutured immediately or within a few hours, and the results will be satisfactory if there is no dyscrasia. In secondary operations, not every laceration of quite considerable extent, of cervix or perineum, need be repaired; it is only when there is some pathological condition present, dependent on the laceration, that it is necessary to operate. No patient wants to submit to an unnecessary operation, and no true surgeon wants to perform it.

Version.—Version may be defined as the changing of one portion of the fœtal ovoid, which presents, for another. There are three varieties and three methods of operating. I have made the following diagram to show them at a glance. It is seen that podalic version has but two methods, while the others have three.



External manipulations for the production of version were practised by the earliest races. The ancient Mexicans and Japanese subjected their women to massage in order to cause a vertex presentation. Only of late years has external version become a popular obstetrical operation. Hubert de Louvain demonstrated its advantages in 1845, and within a short time Tarnier, Chautreuil, Budin, and Pinard have written on the subject.

The external method of version may be either cephalic or pelvic. Pinard strongly insists on the external method when the breech presents, and says it is dangerous neither for the mother nor for the child. In the primipara it is sometimes difficult, and may be impossible. We should, however, always attempt it, and it usually can be performed. Pelvic presentations are generally serious in primiparæ on account of the greater resistance of cervix

and perineum. They are not as a rule dangerous in multiparæ, and therefore external version is not necessary in these cases, but may be performed if it is desired. Transverse presentations are an absolute indication for external version. It is also indicated in pelvic deformity, and in placenta prævia. It is counter-indicated as a rule during labor.

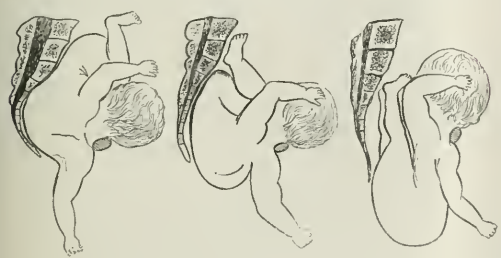
Method Before Labor.—1. In transverse presentations, apply one hand to the vertex, and the other to the

Fig. 5.—Cephalic Version, External Method

breech, and then by slow, continued pressure in the opposite direction, bring them around to the median line. (Fig. 5.) Pressure on the head alone may suffice if the child is small and movable. 2. In breech presentations, press the head down in the opposite direction to the breech; the pressure must be slow and continuous.

Method During Labor.—Apply pressure only between the pains, and during a pain hold the fœtus in position, so as not to lose the ground gained. When the head is engaged, the membranes may be ruptured if there is a tendency to displacement.

Pelvic Version.—The operation of pelvic version has seldom been performed manually, and has not yet been properly described, its advantages being known but to a very few. Obstetric works have rarely referred to it, and where they have done so, half a dozen lines was considered enough to devote to its description. This seeming neglect of such an important operation is to me a most unfortunate error, and one which should have been corrected long before this by practical obstetricians. It is stated that spontaneous pelvic evolution is quite a common occurrence, and I think it would be more often ob-



Figs. 6, 7, 8.—Spontaneous Evolution.

served if the attention was more especially directed to it, and if physicians were not so prone to interfere with nature's methods. It is more readily accomplished when the pregnancy has only advanced to the seventh or eighth month, and it is probably more common at this time than later on, when the child is larger and when it more fully occupies the uterine cavity. Velpeau has collected a hundred and thirty-seven cases of spontaneous evolution, which certainly shows it is comparatively frequent. In cases where the child is dead and the shoulder situated low down in the pelvis, the uterine contractions, assisted by the anatomical conditions present, cause the spinal column to readily become doubled upon itself anteriorly; for the abdomen having no bony structure, and the spinal column no spinous processes in front, its anterior flexion is most easily produced. Spontaneous pelvic evolution (Figs. 6, 7, 8) occurs far more frequently than spontaneous cephalic evolution, the latter being quite rare, and is due to the same factors working in the opposite direction. This difference results from the flexibility of the lower portion of the body of the child. In spontaneous pelvic version the breech presents and the head and trunk pass to the fundus (Fig. 9). This occurs much more frequently than the preceding, but it is impossible for it to take place when the uterus is retracted and moulded to the fœtus. The natural mechanism of spontaneous pelvic evolution can be readily produced by the obstetrician, because the artificial efforts supplement and assist the natural ones, following as they do in the line of nature's method of delivery. Pelvic version, in these cases, is nothing more than the imitation by artificial efforts of spontaneous pelvic evolution (Figs. 6, 7, 8), and is most frequently indicated in transverse presentations.

Fig. 9.—Spontaneous Pelvic Version.

This method of delivery has rarely been performed by the obstetrician. Kleinwachter says it is indicated in cases where the breech lies closer to the inlet than does the head, and where it would be difficult or impossible to perform the operation of cephalic version. It may be performed by external manipulation, but it is more easily accomplished by the combined method. When the latter method is chosen, the obstetrician should insert his fingers in the child's groin, or over the crest of the ilium (Fig. 12), and gradually draw the breech down into the pelvic basin. This finishes the operation of pelvic version, and now the operation of extraction can be easily performed. Where the child is small or medium size, we may rarely wait for natural delivery; if, however, it is large and the delivery promises to be difficult, you may give assistance by applying the forceps to the breech, or manual extraction may be employed. Spontaneous expulsion resulting from uterine contractions sometimes takes place in transverse presentations, where the shoulder presents and the body is well down in the pelvis. Denman has cited many cases in which this has occurred, but we should not think of depending upon nature to effect delivery in this way. Where artificial delivery has been resorted to under these circumstances, it has been hitherto the custom to perform the operation of podalic version. I recommend, however, as the result of my experience, the performance in many cases of pelvic version instead; its advantages over podalic version in these cases of transverse presentation, are as follows:

1. It is a much simpler operation, as it simply converts a case into an ordinary breech presentation.

2. It necessitates the introduction of the fingers only into the uterus, while podalic version requires the introduction of the whole hand and often most of the arm.

3. The child need only be moved sufficiently to draw down the breech, while, in most cases of podalic version,

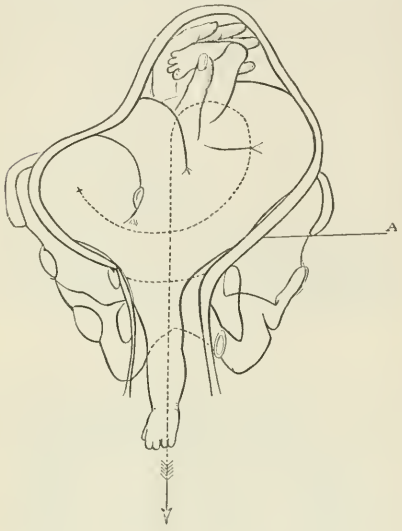


Fig. 10.—Podalic Version, Internal Method. A, Danger point.

the child must be made to rotate around the whole cavity of the uterus (Fig. 10).

4. There is much less risk of rupturing the uterus.

5. There is much less shock attending the operation.

6. For the above reasons, the mortality for both the mother and the child is much less than in podalic version.

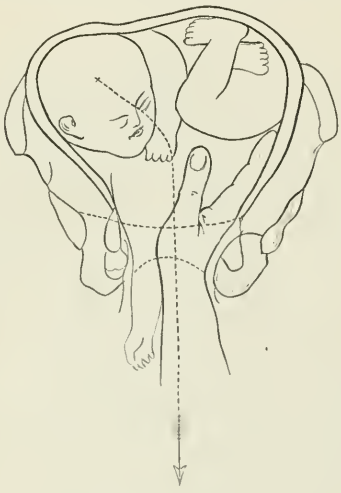

Fig. 11.—Pelvic Version, Internal Method.

In the operation of podalic version (Fig. 10) the body and head ascends to the fundus before the delivery begins, thus making the circuit of the interior of the uterus. In pelvic version, this does not occur, the breech being drawn down at once and the body and head following immediately. They traverse, at most, not more than a fourth of the circuit of the uterine cavity (Fig. 11). In cases where the uterus is strongly retracted upon the body of the child, podalic version is extremely hazardous, not only on account of the profound shock which it causes, but the great danger of rupture of the uterus. Podalic version is often employed for conditions where the forceps or pelvic version is indicated, and its performance in cases where there is thinning of the lower portion of the uterus has been the cause of many deaths from uterine rupture and from shock. In transverse presentation, where the child is alive and movable without great force being employed, cephalic version may be attempted in the intervals of the pains, the uterus meanwhile being thoroughly relaxed by morphia or chloroform. If this is not feasible, it will generally be found that pelvic version can be employed. If the examination during the last month of pregnancy shows that the presentation is not cephalic, it should be rectified,

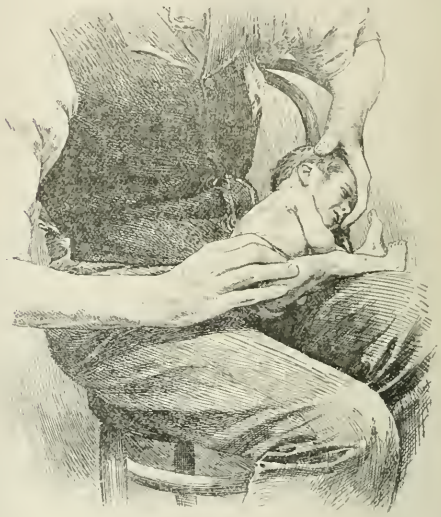

Fig. 12.—Method of Seizing the Breech in Pelvic Version.

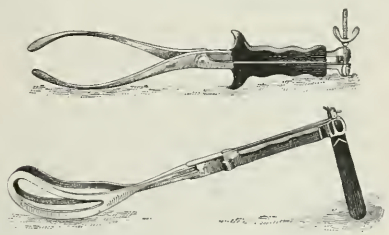
and, if during the labor the presentation is neither cephalic nor pelvic, the child should immediately be turned in either direction. In performing the operation of version, the pressure should be such as to shorten the long axis of the fœtal ovoid, and to place it in its proper relation to the pelvis. The pressure, therefore, should be made upon both head and breech, producing flexion and approximating the two poles of the fœtus. If we are not successful with external manipulation, the external hand should press the head and shoulder of the child upward, but not too strongly, while the internal hand at the same time draws down the breech. The breech may be drawn down by the thumb and two fingers of the operator grasping the child's pelvis with their extremities over the iliac crests or in the groins (see Fig. 12). When the version is complete, if the operation of immediate extraction is indicated it can be accomplished by continuing the manual traction, or the forceps may be employed for this purpose. This may seem to be a decided innovation, but it is the result of practical experience. We should not confound version and extraction, they being two distinct operations and each having its own special indications. The cases in which pelvic version is especially indicated are those unfavorable ones of arm presentation with the shoulder low down in the pelvis, and where the uterus is strongly retracted on the child's body and the membranes have been ruptured. Podalic version, as ordinarily employed, is here out of the question. You must

not confound podalic extraction with podalic version, as the former may be employed with pelvic version. Although podalic version is most frequently performed, and is recommended for all sorts of conditions, I am far from believing that it is a panacea for every obstetrical ill. In the ordinary pelvis, with a child of moderate size, the operation of pelvic version is not difficult, and, when skilfully performed, will often obviate the necessity of decapitation. The following case is indicative of its advantages in a common condition:

Mrs. W——, aged twenty-five, wife of a physician. First pregnancy normal. During her second, nothing unusual occurred until the ninth month, when an accidental blow on the abdomen caused slight uterine hemorrhage, followed after a few days by labor pains. On examination a dorso-anterior transverse presentation was found, which it was attempted to rectify, under chloroform, by the performance of podalic version. Alarming symptoms arising, she was given morphia hypodermically to quiet the pains until I arrived. The patient was well narcotized and the uterus was found completely retracted upon the body of the child; the left arm and about two feet of the umbilical cord were found protruding from the vulva; the arm was bluish and swollen, and the cord cold and pulseless. Owing to the retraction of the uterus and its being moulded closely to the body of the child, neither ordinary podalic nor cephalic version could be performed without great danger of rupturing the uterus. As the head of the child lay to the right, I performed the operation of pelvic version by the combined method; introducing my right hand I slipped my fingers into the child's groin, and following the method of nature, brought down the breech, thus quickly and easily effecting delivery.

Symphyseotomy.—Although it is generally thought that symphyseotomy was first proposed by Jean René Sigault, a French student, in 1769, and was first performed successfully by him in 1777, De La Courvée, another Frenchman, did the operation in 1644. It has been kept alive as an operation, and most often performed by the Italians. When it was first proposed, it was rejected by the French Academy and generally decried, the usual fate of most new discoveries. But after its successful performance it became enthusiastically received. After a time, however, it fell almost into oblivion, and it was nearly a century when, in 1866, it was again revived by Morisani. In 1892 it was performed by Spinelli, in Paris, and since that time has become a popular operation. The first performance of it in this country was by Dr. Jewett, of Brooklyn, followed by Hirst, of Philadelphia, who was shortly followed by Dr. Garrigues, of New York. Since 1886, under aseptic surgery, there has been sixty-eight operations and sixty-five women saved, and the three deaths were due to other causes. Pinard and his associates, in Paris, have operated on twenty women, who have all lived. There were but two deaths of children, making a total of thirty-eight lives saved out of forty. The rehabilitation of this operation, and the condemnation of craniotomy upon the living fœtus by progressive obstetricians, especially shows the advance in the field of obstetrics which has taken place within the past few years. This operation is often called Sigaultean operation, in honor of its first proposer. It limits the field of Cæsarean section most decidedly, and leaves to it the sphere only of absolute indication. It is an operation especially indicated where the patient has been exhausted by long and hard labor, and is here much less fatal than Cæsarean section. It is very important to take proper measure of the conjugata vera of the pelvis, and also to determine if the sacro-iliac synchondroses are normal, and whether coxalgic anchylosis be present. It is also contra-indicated in cases of cancer of the cervix and where the cervix cannot be dilated, also in pelvic tumors and exostoses causing great obstruction. The results obtained in symphyseotomy since the introduction of antiseptic methods are certainly remarkable, the wounds of the soft parts and pubis healing readily by first intention. The great advantages over Cæsarean section are its simplicity, that the peritoneum is not invaded, and the uterus not disturbed in any way. It is an operation which has banished from the domain of obstetrics craniotomy on the living fœtus, and the induction of premature labor is now no longer necessary. Cæsarean section should now only be performed for its absolute indication, where the conjugata vera is two and a half inches or less. Symphyseotomy can be repeated on the same patient, and has been so performed in several instances.

It is a very simple operation. After shaving the parts and having rendered everything aseptic, a catheter is inserted into the urethra to depress it out of the reach of injury. The incision should be made above the pubis, large enough to give free access to the joint. At the upper part of the symphysis a large vein may sometimes be found, which will require ligation. In some pelves the symphysis is flat and of great height. The recti muscles should be separated for a short distance from the bone, and after sliding the index-finger against the posterior surface, glide Galbiati's knife along the finger and cut from below upward, forward, and outward. The bladder and urethra must be carefully avoided when carrying the knife through the articulation. After the incision the bent knees are abducted, causing a separation of two and a half inches at the symphysis. If the adduction is carried to four inches or more, it will cause the sacro-iliac articulations to be torn open and grievously injured. While the limbs are fixed and abducted by the assistants, the delivery of the child is accomplished. The incision is then sutured, and the wound dressed antiseptically, and the pelvis carefully bandaged. Broad straps of adhesive plaster are drawn around the hips and over the abdomen, or gypsum bandages may be used. The dressing of the wound should be renewed daily. The patient should be kept in bed from three to four weeks. In these cases there is almost always more or less asphyxiation of the child. This should be prepared for, and the usual measures adopted. The child's head should be measured to determine its development. After delivery, if it is thought necessary, a tampon of iodoform gauze can be placed in the uterus and vagina. In some cases the joint surfaces are irregular like the letter S, and are also completely ossified. This makes the use of a symphyseotomy knife quite difficult, and here a surgical chain-saw may be employed, and when bone tissue is severed the union becomes even more firmly united. This operation completely occupies the position between the forceps, or version, and Cæsarean section, and with our thorough asepsis this is, like all others, virtually a new operation. It increases the diameters of the pelvis and changes a contracted into a spacious one. The



Figs. 13 and 14.—Author's Compression Forceps.

transverse and oblique, and in fact all diameters, are increased in a proportion of one-fourth to one-half of the distance of the separation of the symphysis. If the separation is two and a half inches, the general gain is about one inch in all directions. Pubiotomy is indicated where the conjugata vera is anywhere between two and a half and three and one-fourth inches. Above three and one-fourth inches the forceps or version is indicated, preferably my axis-traction (Fig. 1), or my compression forceps (Figs. 13 and 14). Nothing has given me greater satisfaction than to find that, when other ordinary forceps slip and fail to deliver, my instrument generally does the

work easily (Figs. 1, 2, and 3). The operation is also indicated in difficult face presentations, and in difficult cases of craniotomy on the dead child. The risk to the mother by the operation is very slight. Dr. Jewett, of Brooklyn, the first operator in America, says "a properly conducted symphyseotomy is a simpler and safer procedure than difficult high forceps delivery."

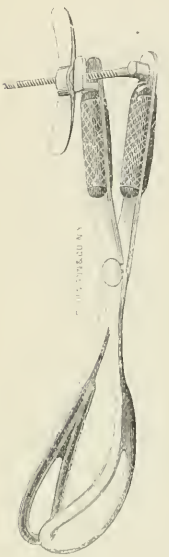


Fig. 15.—Lusk's Cephalotribe.

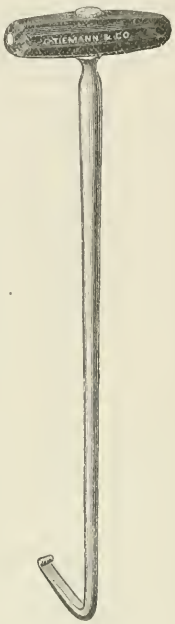

Fig. 16.—Braun's Hook.

Embryotomy.—With obstetricians possessed of the proper amount of skill, this operation will be only performed for its absolute indication on the dead child. With the increased knowledge that comes with unbiased and intelligent experience, the time has arrived for a decided change in the views of many obstetricians. Science has progressed, and faulty appliances and ignorance are no excuse for bungling work at this time, when the best skill should be easily obtained. Incompetency cannot here justify itself. We all know how often embryotomy has been performed, when turning, the forceps, or dependence on nature's powers were indicated. There is no comparison to be made with symphyseotomy of the dangers of an attempt to extract the mutilated remains of the child through a conjugate of from two and a half to three inches, an operation of the greatest danger and difficulty, requiring great dexterity and often a lengthened period of time. The shock, the vaginal lacerations, and the dangers of sepsis are great factors. Shock frequently kills the mother within a few hours. Then contrast, if you will, pubiotomy, its easy performance, its simplicity, its safety. Any surgeon of ordinary skill or recent graduate can readily do it. There is a great deal of sophistry in connection with embryotomy, the frequency of its performance on the living child depends entirely upon the individual and his judgment; one operator performs it in about every two hundred cases; another in about every two thousand, and still another in over twenty thousand cases never saw its necessity or countenanced its performance. Below two and a half inches the improved Cæsarean section is indicated. The alternative of turning when unsuccessful, and the child dying from pressure on the cord, allows basiotripsy or cephalotripsy. The best instruments for use in these cases are Braun's (Figs. 16 and 17). I will not, in this article, consider the improved Cæsarean or the Porro-Veit Cæsarean operation.

Clinical Department.

GUMMÆ OF THE LUNG.[1]

By J. A. THOMPSON, M.D.,
CINCINNATI, O.

Sallie M——, aged twenty-two, is a sporting woman. She is about five feet five inches in height, and unusually well developed. Her weight when in good health was one hundred and seventy pounds. Her health had been perfect until she contracted syphilis, four years ago. The first manifestation of this disease was a local sore followed by an eruption about the genitals. She was treated about six months at this time by a physician well-known to the demi-monde of Cincinnati. One year after the first symptoms appeared, a secondary eruption developed on the face. She went to a good regular practitioner at this time, and was treated about one month, when the eruption disappeared, and she stopped taking treatment. The first symptoms of disease of the lung were noticed in April, 1891. She began to cough and have fever, hectic in type. There was constant pain in the back below the right scapula, with marked tenderness on pressure. The expectoration was very profuse and extremely offensive. The cough was worse at night. The right side of the chest was so painful that she could not lie on it. Hemorrhage from the lung followed any unusual exertion or excitement. Her strength failed gradually, and she lost forty pounds in weight. During this time she was under constant treatment by able members of the profession, so that medicines given by the stomach had been thoroughly tried and had dismally failed.

In January, 1893, she became a patient of Dr. C. W. Orr, by whom I was called to see her in consultation. Her condition at that time was as follows: Weight, one hundred and twenty-seven pounds. She was confined to her bed most of the time. The cough was incessant, night and day, depriving her of rest and causing her to vomit her meals by the severity of the paroxysms. The matter expectorated was a mixture of blood, mucus, pus, and caseous *débris*. It was exactly like the discharge that follows the breaking down of a superficial gumma, and contained shreds of necrotic connective tissue. The amount by actual measurement was one quart daily. It was so offensive that her nurse could not remain constantly in the room. The temperature varied rapidly, as septic fevers do, but was usually 104° F. in the evening, and 101° F. in the morning. Physical examination showed the absence of the respiratory murmur over the right lung posteriorly below the scapula. In front, within the mammary line, extending from the third to the fifth intercostal space, was a circular dull area three inches in diameter. The left lung was normal. Examination of the sputum revealed no tubercle bacilli. The clear history of syphilis, beginning two years before the lungs were involved, the limitation of the consolidation to the lower lobe of the lung, the presence of a gummatous ulcer on the left leg, the character of the sputum, and the absence of the tubercle bacillus, justified a diagnosis of gummæ of the lung. The mass was breaking down, and the general symptoms were due to septic absorption. General treatment had failed to benefit her, and unless

[1] Report of a case to the Academy of Medicine, September 25, 1893.

other means of relief were speedily found, a fatal result was inevitable.

I advised the Downie treatment, tracheal injections of menthol and guiacol dissolved in oil. By this method it was possible to treat the abscess cavity, in part, as we would if it were superficial and accessible to direct medication. Every intelligent practitioner knows we have no medicine which will check acute suppuration when given internally. Our reliance is on topical measures. The Downie method makes it possible to do for the lungs what we do in external abscesses. While we cannot confine our pulmonary treatment exactly to the diseased spot, the antiseptics used being volatile at the temperature of the body makes it certain we can reach any focus of disease to which the bronchial tubes are still open. The rapid absorption of the vaporized remedies, too, makes it possible in this way to procure quick and notable constitutional effects. In the present case the remedy used was guiacol one per cent., menthol two per cent , sol. in liq. albolene. One drachm was injected at a time. This was of course a very small dose, but it was enough to produce marked effects from the first. Menthol given in this way has a marvellous influence in controlling cough. In consumption, with unusually severe cough, two grains of menthol by tracheal injections will control it for twelve hours. The effect in this case was not so lasting. From four to six hours of rest were secured at first. As the secretion diminished and became less purulent from the antiseptic action of the guiacol, the anæsthetic effect of the menthol became more pronounced, so that there would be little cough for ten or twelve hours after the injection. By giving the treatment in the evening the patient was enabled to retain her supper, which she had before vomited, and to get ten hours of refreshing sleep. Daily treatments were continued for two months, Dr. Allen kindly seeing her during my illness.

The history of the case was one of rapid improvement from the time the first injection was given. The fever diminished rapidly, and was gone in three weeks. The amount and character of the expectoration changed quickly for the better. Night-sweats were not noticed after the first two weeks. Several slight hemorrhages occurred, but were never severe. Appetite returned when the paroxysms of cough were controlled, so that she no longer vomited. She gained rapidly in flesh and strength. About six weeks after I first saw her, the breaking down of another gumma in the lung made her very sick for a week, but a continuance of the injections soon controlled the symptoms. During the third month injections were given every second day, or at longer intervals. The constitutional treatment during this time was a continuation of potassium iodide in large doses until the eruption appeared, and then McDade's formula was substituted. Some mild intercurrent illnesses, (diarrhœal attacks) were treated by Dr. Orr. I cannot give any details, because I do not meddle with the general treatment of a case sent to me for special treatment. The attitude of the profession is wrong in this relationship. The specialist is the assistant, not the master of the general practitioner. He should control only in his own work, advise in the general treatment if desired, but the general management of the case belongs to the family medical adviser.

The present condition of the patient is most gratifying. She has gained her normal flesh and strength, she has no cough. Only a little harshness of the respiratory murmur shows where the former consolidation was located. The portion of the lung that collapsed from closure of the bronchi has expanded, and the normal murmur is heard over it. I see her occasionally with small ulcers in mouth or throat, showing that the syphilitic poison is still active. But the cure of the lung trouble is complete.

The reasons that made me choose the Downie treatment for this case apply equally well to cases with tubercular cavities in the lungs. These become, through secondary infection by germs of suppuration, practically abscess cavities. Much of the fever and all the night-sweats of consumption, it is reasonable to suppose, are due to septic absorption. The rational plan of treatment is to disinfect the suppurating cavities, and in the lungs this can only be done by tracheal injections. The cough of consumptives can be controlled for hours by this method. Final results will probably not be as brilliant as in pulmonary syphilis, but the relief afforded the sufferers makes the method one worthy of more general use.

A CASE OF ACUTE IDIOPATHIC GLOSSITIS.

By CLINTON WAGNER, M.D.,

NEW YORK.

J. B——, aged thirty, a native of Roumania, occupation carpenter, was admitted into the Metropolitan Throat Hospital suffering from acute idiopathic glossitis. With great difficulty he made the following statement: About five days ago his tongue became painful and very sensitive to the touch, upon the superior or dorsum surface, near the tip or anterior extremity; swelling of the organ rapidly followed. At the time of his admission into the hospital the tongue was enormously swollen, œdematous on the lateral and under surfaces; the dorsum tense, firm, and rigid to the touch, indentations from pressure against both the upper and lower teeth; it filled almost entirely the oral cavity and protruded considerably beyond the lips, there was constant dribbling of saliva; speech almost impossible; he was very weak, respiration laborious, expression anxious and indicating intense suffering; deglutition greatly interfered with, and unable to swallow nourishment, except milk, slowly, and in very small quantities at a time. There was no history of syphilis, nor evidence of tuberculosis, nor had the tongue sustained in any way a traumatic injury. A careful digital examination failed to detect an inflamed condition of the maxillary bones, or an alveolar abscess; his teeth appeared to be in good condition and unusually well preserved. The sublingual gland was swollen, firm and hard, and imparted no sense of fluctuation to the touch, but on the right side, and near its posterior border, was extremely sensitive to pressure. At this point I made a free incision from which escaped an enormous quantity of thick, creamy, fetid pus. A probe was introduced, which I carried several inches upward and backward, showing that the body of the tongue was involved, and was undoubtedly the source of the pus. With the escape of the pus subsidence of the swollen tongue began.

REPEATED AND PROFUSE HEMORRHAGE SUBSEQUENT TO PUNCTURE OF A MEIBOMIAN CYST.

By FRANCIS M. CHISOLM, M.D.,

BALTIMORE, MD.

THE subjects of hæmatophilia are comparatively so few that it is seldom one comes under the care of the ophthalmic surgeon. Now and then, at long intervals, one appears; and since the physical development of these so-called "bleeders" differs in no way from an ordinarily healthy and robust person, it is only after the surgical work is done that their peculiarity is manifest.

The following case, coming recently under my care, was a well-developed, muscular mulatto man, thirty-five years of age, weighing one hundred and seventy-eight pounds, whose only deviation from health had been an occasional sore throat. The annoyance for which he sought treatment was a small, painless tumor on his right upper eyelid, diagnosed a tarsal cyst. The operation for its removal was by puncture into the sac from the conjunctival surface, the contents expressed, and the interior of the sac curetted. Only a few drops of blood were lost during this procedure, and the patient was dismissed with instructions to return for inspection in a few days. A mild astringent, antiseptic lotion was given him to drop in the eye. Four days after the operation he came to the office

with his eye bleeding profusely, covered up with two handkerchiefs, both saturated with blood. This was the fourth attack of bleeding, he said, since the operation. One was on the afternoon of the second day, another that evening, and the third late that night. This last continued several hours before it stopped spontaneously; the previous ones had been arrested by a liberal use of hot water. The hemorrhages were without provocation, came on suddenly, and were copious enough to saturate three or four handkerchiefs. Relief had come only after several hours' duration. He thinks the loss from the night bleeding alone was fully one pint. Examination of the eye showed that the hemorrhage was from the puncture in the lid made for the emptying of the cyst. A galvanocautery loop was first applied to the wound, with the hope of putting an end at once to the bleeding, but on removing the pressure of the ring forceps, blood continued to well up from the puncture as before the cauterization. A deep stitch was then taken across the wound and the threads drawn tightly. With the opening thus completely closed, all bleeding was permanently stopped. On inquiry, this man recollected that in previous years he had had teeth extracted, with so much hemorrhage following, that a physician had to be appealed to for relief. There had been no recurrence of the trouble when I again saw him, three days after the application of the suture, and the lid looked well.

PAINLESS DENTISTRY.

By ROSWELL O. STEBBINS, D.D.S.,
NEW YORK.

For fourteen years I have endeavored to devise and adopt methods in operating upon teeth, for very sensitive and nervous patients, with as little pain and shock to the nervous system as possible. Sharp, well-tempered instruments, of proper shape, in the hands of a careful operator, will cause less pain in excavating the cavity of a tooth, than the best local anæsthetic or obtundent applied to the tooth, if dull, ill-shaped instruments are used with force enough to crush down the tooth structure, which is generally the case, as the majority of dentists are not mechanics, or do not care to soil their hands and take the time to make, or obtain, the proper instrument to be used.

The dental engine, so often looked upon as an invention of torture, has gained this unenviable reputation by the improper use to which it has been put; the motive power, over which the operator ofttimes has no control, propels the instrument with such rapidity that the friction causes intense pain, more especially when the drill or burr is dull. When the regulating of the speed of the wheel is under absolute control of the operator, the excavating of a cavity by the use of a sharp drill or burr, of proper size, causes so little pain or discomfort that the most sensitive patient does not object to its use. Yet in many cases it is the fear and dread that the instrument will cut a little too near the nerve, and that the operator will not stop when asked, as he has promised, that upsets the patients' nerves, leaving them in an excited condition that increases the possibility of causing pain tenfold. To gain the confidence of patients and assure them that you are aware that a very sensitive organ is about to be operated upon, and that you will use every means to avoid hurting them, will greatly lessen the possibility of causing pain. For patients to know that it would be in their power to stop the engine instantly, without the knowledge of the operator, would so lessen the dread of the use of the engine, thereby facilitating the excavating of a cavity, that the most sensitive patient would not object to its use. I have devised a break by which the patients, with a cord held in their hand, can stop the engine instantly, and with the assistance of an obtundent, can truthfully say that more than the majority of operations in dentistry can be made painless.

The brake consists of a pair of pliers, one handle of which is made fast to the upright of the dental engine; the other handle is closed by pulling the string which the patient holds, thereby clamping the belt, and stopping the engine instantly.

55 West Forty-fifth Street.

A NEW AND RAPID METHOD OF ANÆSTHESIA.

By WILLIAM S. MAGILL, M.D.,
CHICAGO, ILL.

As the first American to employ this method, it may be permitted me to invite the attention of American surgeons to this subject by this brief notice.

The method was devised and developed, during the summer and fall of 1892, by Dr. Bourbon, anæsthesist of Hôpital Bichat, Dr. Hartman, acting surgeon, and myself, and, since its introduction, is the preferred method in the surgical service of Professor Terrier, at Hôpital Bichat. The modus operandi cannot be better described briefly than is done by Professor Terrier, in his communication of the subject to the Société de Chirurgie of Paris,[1] October 19, 1892.

"The bromide of ethyl should be given in large doses. After pouring it abundantly (about three grammes) upon a folded towel, it is placed over the nose and mouth of the patient, who is told to breathe deeply. Generally at the second or third inhalation a slight agitation appears, but at the fifth or sixth the anæsthesia is complete, with total loss of consciousness. With the continuance of this anæsthetic, in a moment, sometimes preceded by tonic contracture, the complete muscular resolution is accomplished, with congested face and dilated pupil. At this moment the towel saturated with ethyl bromide is rejected, and another upon which chloroform is poured, is substituted in its place, without allowing any interruption of anæsthesia in changing. The first dose of chloroform only should be fairly strong (one gramme). At this moment the operation may be commenced (about three-quarters to one minute since the commencement of the anæsthesia). The facial congestion diminishes little by little, the pupillary dilatation gives place to retraction; in a word, the transition from the anæsthesia of the bromide to that of chloroform is accomplished without the slightest interruption of the sleep. From this moment the continuance of the anæsthesia is done in the ordinary way (chloroform in small and regular doses). The difference is simply that the complete anæsthesia is immediate, instead of resultant of a period often long which is necessary in the process of chloroform anæsthesia." [And more so in case of employment of ether.]

The matter in brackets is not a part of Professor Terrier's communication, but inserted as explanatory.

It will be seen that the duration of the anæsthesia may be prolonged at the will of the operator. Experience has demonstrated that by this process a remarkably small quantity of anæsthetic agents suffices for complete and protracted unconsciousness, and that by reason of the smallness of the quantity used, the awakening of the patient almost immediately follows the cessation of administering the chloroform.

I have performed a complete anæsthesia for ovariotomy by Professor Terrier, with the administration of three grammes of ethyl bromide and twelve grammes of chloroform, recovery from sleep immediate, and no subsequent nausea. Duration of the complete anæsthesia thirty-two minutes.

This is only one of many similar cases which will be found in the publication of the clinical studies. How many anæsthesists are there who can obtain a complete resolution of a vigorous subject with twelve grammes of chloroform only?

[1] Bulletin de la Société de Chirurgie, vol. xviii., No. 10, November, 1892, pages 626-627.

The advantages claimed for this method are:

1. Rapidity, a complete anæsthesia, which allows the commencement of the operation in one minute's time after the first inhalation of the anæsthetic.

2. Doing away with all violent agitation on the part of the patient, so common when chloroform or ether alone is used.

3. On account of the dissimilar physiological action of the two anæsthetics employed, the dangers attributed to the use of chloroform alone are in a great measure eliminated by the counter-action of the ethyl bromide previously administered.

4. An almost entire absence of post-operatory nausea.

In February of this year this method was introduced in the service of Dr. Segond, at the Maison de Santé, the City Hospital of Paris, by Dr. Malherbe, and immediately adopted by Dr. Segond for all of his work, to the exclusion of other methods. It was my privilege to introduce this method in the service of Dr. Monod, at Hôpital St. Antoine, in April of this year, which led to its adoption as the current method throughout his wards. Dr. Richelot, of Hôpital St. Louis, has spoken with considerable favor of this process of anæsthesia, in the discussion at the Société de Chirurgie, and I am informed that in his service he employs it in preference to all others, in cases where affections of the heart cause any apprehension from the use of chloroform alone.

The patients who have been subjected to this method of anæsthesia by my colleagues and myself have pronounced in its favor, and in cases of an anæsthesia to be repeated for them have asked for this method.

Convinced of its general utility, I would invite its trial in the work of American surgeons, that it may be widely known, experimented, and thoroughly studied and discussed.

In a short time a monograph on the subject with complete bibliography, chemical and physiological aspects, and several hundred detailed clinical studies of its application, will be published in Paris as a complete history and introduction of the subject. There appears to be no element of danger in the combined employment of these two agents for a complete anæsthesia, and the simplicity of its application will be evident on trial.

A CASE OF STRAMONIUM INTOXICATION.

By CHARLES O. MAISCH, M.D.,

NEW YORK.

The comparative rarity of these cases, at least in our larger cities, and the marked manifestations exhibited in this instance, lead me to place it on record.

Some three months ago, I was summoned early in the morning to Mrs. B——. The impression made upon me was that I had to deal with a case of acute alcoholism. Patient, a woman about thirty years of age, well-developed, robust and healthy in appearance, retired perfectly well and sound, one hour before, and fell asleep shortly after lying down. Had not been exposed to any contagion, "nor had she taken any stimulants or medicines." Shortly after falling asleep her husband noticed that she became very restless, "breathing deeply and loudly," and upon rousing her, she appeared "out of her mind and wild." Pulse, 130 and thready; temperature, 100.2° F.; pupils markedly dilated; conjunctivæ deeply injected and reddened; eyes wildly staring and restless. Face and chest covered with an erythema like that of scarlatina or that caused by belladonna. Tongue and fauces dry and parched; respirations shallow and increased to 35 per minute. Wild and active delirium; hallucinations of sight and hearing. Complains of intense thirst and severe frontal headache. Patient almost unmanageable, throwing and breaking everything within reach, and constantly looking under bed and searching closets for strange men and animals.

The symptoms were those of atropinismus, and after administering copious draughts of warm water, salt, and mustard to gain time, I gave morphine sulfuric 0.03 (gr. $\frac{1}{2}$) subcutaneously.

Upon declaring to her husband that the patient must have imbibed something that was poisonous, he learned from a servant that her mistress had taken some kind of tea before retiring.

Upon being shown what remained, I recognized the toothed, ovoid thorn-apple leaves, the bitter, pungent, and metallic taste that is peculiar to it.

On further search a package of compressed stramonium leaves, such as is sold in the stores, was found. Diagnosis was established.

One hour after the exhibition of the morphine salt, the patient was resting quietly; an ice-bag had been put to her head and morphine sulfuric 0.015 (gr. $\frac{1}{4}$) was ordered every four hours, and cold black coffee for the thirst, which still was intense. The next forenoon, when I saw my patient, she had become perfectly rational; the erythema had disappeared, as had also the throat symptoms. She had not the least recollection of what had occurred during the night after having taken the tea, which was intended to restore her menstrual flow. The mydriasis lasted for almost four days.

It may be of interest to know how much of the drug had been taken. The package contained one ounce of the dried leaves, of which one-half had been used in preparing the infusion; to this was added a cup (eight ounces) of boiling water, and after standing one-half hour, she took two tablespoonfuls. From this we may deduce that one ounce of an infusion of the strength of 1 to 16 (considerably weaker than is officinal [1 to 10]) caused toxic effects in this case.

The quantity is certainly not a large dose, and it is to be presumed that the woman has an idiosyncrasy for the drug.

Patient made a complete recovery.

90 MADISON STREET.

Progress of Medical Science.

A Caution in the Use of Trendelenburg's Posture in Cœliotomy.—In the current number of the *New York Polyclinic*, Dr. H. C. Coe, of this city, sounds a note of warning with reference to the now commonly employed inclined posture in abdominal surgery. "There is," he says, "danger of secondary hemorrhage. When a patient lies for an hour or more with hips elevated, the blood-supply to the pelvis is naturally diminished. The return to the dorsal position determines an increase in the venous return. This ordinarily occasions only a trifling oozing which causes no anxiety, but there may be a going over beyond the line of danger, as his experience shows."

His remarks are accentuated by the careful record of two cases which proved fatal from this very cause. In the first case cœliotomy was done for an intra-ligamentous cyst on the right side and a smaller ovarian cyst on the left. The latter was adherent to the pelvic floor and to the uterus. Both tubes were found free from pus, but were thickened, enlarged, and adherent. After enucleation in the usual manner, with but little loss of blood, the customary technique was followed in regard to closing all bleeding points. After lowering the patient to the dorsal position the pelvis, which had been packed with sponges, was again carefully examined, and its cavity packed with strips of gauze to stop the slight oozing which still persisted, and the ends of the strips were brought out through the lower angle of the abdominal wound. At the close of the operation the patient's general condition was not good. Pulse was 130 and there was much shock. The house surgeon, upon his own responsibility, elevated the foot of the bed eight inches, but the patient showed all the evidences of internal hemorrhage, though no oozing appeared on the dressings. Three hours and a half later, a removal of a few inches

of the gauze showed that the latter was saturated with blood. The wound was reopened, clots found and removed, and the cavity irrigated with a hot saline solution. No bleeding point could be discovered. Intravenous saline infusion, oxygen, and hypodermatic use of strychnia and camphorated oil failed to rally the patient, who died in twelve hours after the operation. It had been found on reopening the wound that the hemorrhage had ceased, and death seemed to result from shock rather than from loss of blood. The writer states that, had the patient been kept on the back when in bed, the blood would probably have remained in the pelvis, stained the gauze, and its escape been earlier recognized. It was believed that the fatal oozing was due to venous return immediately after the operation, when the patient was released from the Trendelenburg posture.

The second case was of the same general nature, but on the third day suppression of urine set in and carried off the patient two days later. At the autopsy the ligatures were found to be secure, and it was impossible to locate the exact source of the hemorrhage. A large clot was found dissecting up the peritoneum from the base of the broad ligament, as high as the kidney; it represented fully a pint of blood, which being unable to make its way externally or into the peritoneal cavity, had, as the patient was in the inclined position, gravitated in the direction of least resistance. A similar condition has been noted in cases of subperitoneal rupture of the parturient uterus. The abdominal viscera were normal (there being no evidences of sepsis) with the exception of the kidneys, which were the seat of chronic interstitial nephritis; the latter, in the opinion of the pathologist, was the cause of death.

Dr. Coe regards it as a cardinal principle to be observed in the performance of cœliotomy in the elevated position, that the abdominal cavity should be entirely shut off from the pelvis by flat sponges or gauze pads, so that fluids shall not come in contact with the intestines. If this is properly done irrigation is rarely necessary. In order to prevent secondary hemorrhage, the physician should satisfy himself by repeated examination that the change in posture is not followed by hemorrhage. Time should be taken at the operation to secure every bleeding point, as it is much safer to lengthen the duration of the surgical procedure than it is to reopen the abdomen later. The latter is almost invariably fatal. Of five cases in which Dr. Coe reopened for hemorrhage (two of his own and three for other surgeons), only one was successful; he is cognizant of a dozen other cases in which the result was equally unfavorable. In order to save the patient, the hemorrhage must be recognized promptly, while she has still sufficient strength to stand the manipulation necessary during the second operation. This implies careful watching by an experienced observer (not a nurse), and considerable judgment, since the symptoms of hemorrhage are often so obscure as to be indistinguishable from shock; hence the value of a drainage-tube—perhaps its most useful function.

Finally, Dr. Coe condemns the practice of elevating the bed within two or three hours after cœliotomy. In every case a certain fluid exudate accumulates in the pelvic cavity. If allowed to remain there, it will probably be absorbed. In any event, it is much safer there than diffused among the intestines. To elevate the pelvis when drainage is sought, defeats the very end aimed at. If it is thought proper to elevate the foot of the bed to overcome heart failure or cerebral anæmia, it should be done only after a most searching examination to exclude every evidence of progressing hemorrhage.

Total Extirpation of the Prostate.—According to the Vienna correspondent of the *Medical Press*, Professor Dittel raised this question recently in the Society of Aerzte. In the early part of May a young man, aged thirty-two, a laborer, came to hospital complaining of great loss of blood. The first opinion that was formed was stone in the bladder, but on passing the sound no concretion could be discovered. On pressing well down into the abdomen a large swelling, somewhat elastic, was found at the lower part of the bladder; from the anus the prostate was found greatly enlarged, but its dimensions could not be estimated, as its posterior margin could not be reached. Urination was frequent and difficult, while the catheter gave relief at all times. After exhausting all the phenomena in the diagnosis, it was concluded that the prostate was damaged by some growth. The endoscope revealed a large swelling lying to the right of the channel, in which was a small depression whence the blood slowly oozed out, while the whole surface was smooth and of normal appearance. From his previous experience of removing the prostate he was disinclined to take this step. He therefore resolved on opening the bladder above the pubis, through which he discovered the source of bleeding from the large prominence at the neck of the bladder. With a sharp scoop he removed a large quantity of the smooth surface, but found the morbid growth too extensive for this operation. He consequently resolved on making an opening below, cutting from the coccyx to the anus; he was thereby enabled to enucleate the former, and with an oval incision reached the tumor by the right side of the rectum; the capsule of the prostate was opened and the whole removed. On microscopic examination this was found to be a fibroma, but further classification was deferred at the time. The wound was filled with iodoform gauze and the bladder drained. On the filling of the bladder not a drop could be discovered in the wound, although after a few days a urinary odor was observed on the dressing, which led to the presumption of a perforation being present. Beyond this no other bad symptom has accrued, and the wound is nearly healed. With this favorable result Dittel is now prepared to change his opinion. Prior to this he performed an operation three times without any success, and before commencing the present operation resolved that he would try any other method if possible than extirpation. He is now inclined to believe that there are certain conditions of the urethra that may favor this operation, one of which is its course through the prostate, which he is now convinced lies nearer to the commissura posterior. With this knowledge he thinks the prostate can be more accurately removed without injuring the urethra. In all cases, therefore, where the tumor of the prostate implicates the urethra he is convinced that extirpation is impracticable, as it cannot be performed without injuring the canal, and under circumstances of this kind he thinks it would be better to remove one-half of the prostate. In some cases he thinks posterior or sacral removal would be more advantageous and have a better chance of success.

Pernicious Anæmia and Degenerations of the Spinal Cord.—According to Dr. W. Minnich, Professor Lichtheim was the first to call attention to the occurrence of degenerations of the spinal cord in association with pernicious anæmia (*The Lancet*). This was in 1887, at the Congress für Innere Medicin, the special degeneration which he described being in the posterior columns. The three cases to which he briefly drew attention are more fully described in this paper as well as three additional ones. The first case showed profound anæmia, there were paræsthesiæ in the arms, the gait was slow and feeble, but the reflexes were normal. Evidences of the presence of bothriocephali were present in the stools. Degeneration was found to be well marked in the posterior columns, but the posterior roots were normal. In the second case there were anæmia and weakness, with numbness in the fingers and feet; later there were impairment of sensibility in the lower extremities and loss of the knee-jerks, but no ataxy. The changes in the spinal cord were similar to those in the first case. In the third case there were weakness, anæmia, and sensory impairment in all four limbs. There were also ataxy and Argyll-Robertson pupil, and the knee-jerk was lost. Here, also, well-marked degenerations of the spinal cord were

found in the posterior columns, while the posterior roots and the peripheral nerves were intact. The fourth case also showed marked anæmia, with weakness and paræsthesiæ in all four limbs. The gait was at first ataxic, but later spastic, and sensibility in the lower extremities became impaired. The knee-jerks were exaggerated and there was slight paresis of the bladder and rectum. In the spinal cord there was degeneration in the posterior columns, and also in the posterior part of the lateral columns. In the cervical and upper dorsal cord there were also isolated foci of myelitis. The posterior roots and peripheral nerves were unaffected. Although in this case the characteristic signs of pernicious anæmia were not present, Dr. W. Minnich suggests that it was essentially of the same character as the preceding cases, and that the posterior columns were first affected, the involvements of the lateral columns occurring afterward. The next case showed marked motor weakness of the arms and legs, anæmia, and dropsy. Ova of bothriocephali were present in the stools. There were ataxy of the legs and sensory impairment in all the limbs. The knee-jerk was present. At a later stage there was great weakness of the limbs with much sensory impairment, the knee-jerk was feeble and there was incontinence of urine. The pupils were normal. In the cord there was degeneration in the posterior column and also in the lateral and anterior columns, and again the posterior roots were unaffected. The sixth patient had long suffered from great anæmia, and when he came under observation he was very pale and complained of a feeling of fatigue in both lower extremities. There were marked sensory impairment and pains in the limbs. The knee-jerk was exaggerated and there was loss of control over the bladder and rectum. Delirium was present before death. In the spinal cord there was found a marginal degeneration both in the lateral and posterior columns, while the posterior roots peripherally were intact. All the patients were men and ranged in age between thirty-six and fifty-eight. It is worthy of note that in two of them evidences of the presence of bothriocephali were found. The cases form a most important group, and it may be, as is suggested in the paper, that the sclerosis is the result of some toxic influence which is a concomitant of the blood state. The presence of anæmia, parasitic worms, and nervous symptoms naturally suggests the analogy of beri-beri, in which all three are frequently associated; but in that disease the nervous symptoms are, according to our present knowledge, the result of changes in the peripheral nerves.

Gonorrhœal Peritonitis in the Male.—Circumscribed gonorrhœal peritonitis may occur in men as well as in women. Epididymitis is always present at the same time. Whether the peritonitis is caused by gonococci is not yet determined. The routes of invasion are: 1, the vessels of the spermatic plexus; 2, the vas deferens; 3, the lymphatic vessels of the vas deferens. A case reported by M. Horovitz illustrates the last-named path. A man, thirty-one years of age, contracted gonorrhœa on December 18th. He treated his own case by means of cold applications. On the 29th he was attacked by epididymitis. Suspension, ice, and Epsom salt were employed. On January 1st, he experienced severe pain in the region of the great sacro-sciatic foramen and extending into the hip-joint. The pain was increased by attempts to move the limb. On the following day the temperature was 102.7° F.; the man had a chill, suffered from sharp pain in the right iliac region, and sickness of the stomach. The abdomen was greatly distended and very sensitive to pressure. Recovery took place in three weeks.—*Medical Bulletin.*

Multiloculated Pleural Effusions.—Rudolph draws attention to the practical importance of this form of pleural effusion. The loculi may be quite separate from each other or may communicate. The character of the effusion must depend on the causation; in empyemata the tubercle bacillus, the streptococcus, the pneumococcus play the chief part. The loculi may even contain different kinds of fluid. He records a case in which the patient had an empyema on the left side. After 750 c.cm. of pus had been evacuated, the physical signs over the præcordium remained unchanged. At the necropsy, in addition to a purulent pericarditis and an endocarditis, another empyema was found between the mediastinal pleura and the lung, a situation which the author thinks a frequent one for the second empyema. In the third and fourth cases there was a serous effusion in patients with early phthisis, and it was only when the second loculus was tapped that the physical signs cleared up. Want of correspondence between the amount of fluid and the extent of the dulness is an important sign. Thus the fluid should be measured, and the chest examined after the evacuation. The persistence of fever in the absence of other cause for it should suggest a second loculus. The prognosis depends on the primary disease, and on the recognition of the condition. If the effusions are serous and small, the salicylates are useful. Tapping may be required. If the effusion is purulent the chest must be incised, and according to the author a piece of rib removed.—*Centralblatt für Klinische Medicin.*

A New Method of Reducing Dislocation of the Lower Jaw.—Dr. Roth describes his method of reducing maxillary dislocation as follows: 1. The patient seated in an ordinary chair, the operator stands before him with one foot placed slightly to the right side and the other just in front of the patient and in the middle line. 2. He then flexes himself at the hips and causes the patient to lean forward and to place his forehead at the middle of the operator's sternum—but this position varies with the size of the patient's head. 3. The operator now flexes his head so that his chin grips the patient's head about the upper part of the occipital bone, thus acquiring a firm hold with the head well under control between his chin and chest. 4. The thumbs, protected in the usual manner, are placed in the patient's mouth and the fingers of both hands grasp his lower jaw. The author considers that his method has the following advantages: *a*. The operator has the head under perfect control and perfectly fixed; *b*, the line of force exerted by the operator's hands acts in the same line as the resisting force exerted by the operator's chin; *c*, the operator's elbows, being well flexed, he can exert a greater power by the force acting through the thumbs close to the shoulders; the terminal phalanges will be found to have greater muscular power; *d*, the patient's head is in a better position for reducing the dislocation; and *e*, the operator needs no assistant, and does not inconvenience his patient by excessive pushing and pulling the head about during the reduction.—*The Lancet.*

Ligature of External Carotid.—Lipps (*Archiv für klin. Chir.*, Bd. 42, Heft 1) has collected 130 cases of ligature of the external carotid artery, in 12 of which this artery was tied on both sides at the same operation. Of the total number of cases 32 were fatal, and in only two of these was death caused by the operation itself. In both instances the thrombus in the external carotid extended to the common carotid and gave rise to cerebral embolism. In 10 cases in which the operation had been performed for profuse hemorrhage, death was the result of loss of blood and consequent collapse. The author regards this operation as preferable to ligature of the common carotid in those cases in which either might be considered as applicable. The former procedure is much less fatal in its results, and both external carotids may be tied at the same time without much risk As a rule, ligature of the common carotid should, it is thought, be reserved for those cases in which the surgeon has to deal with a very pressing emergency, hemorrhage, for instance, which could not be treated with any good prospects of success by ligature of the external carotid. The remote results of ligature of the external carotid, the author acknowledges, are not always good, but it is doubtful whether in such cases ligature of the common trunk would have had better results.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, October 21, 1893.

MEDICAL EDUCATION IN AMERICA AND ENGLAND.

THE *Lancet*, in its educational number of September 2d, has devoted some space to education in America. While it tells the truth in most respects, it seriously errs in its final conclusion, viz., that, on the whole, medical education at the best schools in this country is inferior to that in England.

Perhaps any protest against this judgment will be taken simply as an evidence of patriotic vanity. We think, however, that this element in our judgment has been sufficiently considered. Yet we do not hesitate to say that, at the present time, a medical student can get a better training in New York, Boston, Philadelphia, Baltimore, and perhaps some other cities, than in London. It is very generally known, outside of England at least, that the English school has suffered from a steady decadence in the last few decades. This decadence has not been so noticeable as that in Paris, because London was never the teaching centre that Paris has been. Yet at the present time, Paris, with all its defects, ranks even higher than London. We can speak dispassionately here. Every year young men come for advice as to what part of Europe they should go to seek further instruction. Germany is oftenest advised, Paris sometimes, London never, except for some special reason.

The cause, as the *Boston Medical and Surgical Journal* states, is partly the absence of laboratory research, partly the lack of concentration of the medical and surgical teaching. On the other hand, laboratory work is very rapidly becoming an essential part of every American student's course. We have already, in this city and Brooklyn, four richly equipped institutions for this kind of teaching, to say nothing of the post-graduate laboratories.

The deficiencies in the best American colleges are the imperfect preliminary training and short courses. But these defects are being rapidly eliminated and will soon cease to exist. Unless London does something to change its present methods, it will soon become the Valkyrie of medical science.

The Cost of a Medical Education, according to the *Hospital*, is, in London, $400 to $500 per year, for five years, plus $700 to $1,000 in fees, making a total of $2,700 to $3,500. In this city it would be $600 a year for three years, and $300 for fees as a minimum estimate.

THE LONGINGS OF PREGNANT WOMEN.

THERE are certain phases of disease having a basis in clinical observation about which more or less tradition has clustered. Such a one is the longings of pregnant women. Taught to every class of students as a regular accompaniment of the grand condition these unnatural desires are, we believe, the exception in actual practice rather than the rule. Yet the subject is one well worthy of study for it has its psychical as well as its physical peculiarities.

A recent paper, read before the Obstetrical Society of London, by Dr. Giles, gives a careful review of the whole topic. He divides the "longings" into two classes—natural and healthy, or unnatural and unhealthy. He considers especially the former, and bases his views upon a careful analysis of three hundred cases. The cause of these peculiar desires may be due to one of three causes. 1. They are due to a desire for something to check the feeling of nausea. This applies especially to sour things. 2. They are the expression of an instinctive want for some class of food in the altered condition of pregnancy. 3. Dr. Giles thinks that in many cases they are due to a kind of auto-suggestion prompted by a popular tradition and gave evidence in support of this view. He shows that the frequency of longings markedly decreases as parity increases. The subject, he thinks, is important from the point of view of the feeding of infants.

In the subsequent discussion Dr. Doran pointed out the psychical effect upon women of the ancient and deeply rooted tradition that patients were naturally expected to have these longings and consequently they had them. The question naturally arises, Are they mere whims or do they have as a starting-point some actual physiological need? This latter point is very probable in view of the fact that the articles of food longed for are mainly vegetables or things containing the vegetable acids. On the other hand, Dr. Giles remarks that "auto-suggestion" may here play the same part which it does in hypnotism, that is, a patient starting with the feeling induced by the conversation of her friends that she ought to feel certain cravings, unconsciously persuades herself that she does actually experience them. Probably both views are correct, the former explaining some cases and the latter others.

As bearing upon the psychical view we must again lay special stress upon the fact that these cravings are far more common in primipara, to whom the reproductive act is a new experience. They decrease as the number of pregnancies of the patient increase. It is somewhat suggestive that the especial article of food most desired is the succulent apple. It will not escape the notice of either the biologist or theologian that in view of the nature of fair woman's yielding to the wiles of the seductive ophidian, this desire is another illustration of, to the one, reversion of type, and to the other, of inherent original sin.

Another writer upon the same topic calls attention to the "popular belief that unless the craving is gratified the offspring will be marked by an impression or outgrowth corresponding to the article denied to the mother; or, failing this unequivocal sign of evolutional dissatisfaction, that the infant will be restless and discontented until, and unless, he or she shall have partaken of the par-

ticular article or substance demanded." There are not wanting a number of more or less authenticated instances of what sceptics will probably qualify as mere coincidences. The resemblance of the marks with the particular articles of maternal longing will be found almost invariably to require a large dose of faith or credulity to recognize. Thus, only a few days since, a case was recorded in which the mother, having been unable to gratify her craving for apples, the child was born with a pedunculated growth on the arm, which the wiseacres at once described as the fleshy analogue of an apple. The same observation holds good in respect of the comparatively common strawberry mark, which is, of course, neither more nor less than a nævus. Furthermore, these longings appear almost exclusively among women of the neurotic type, and rather curiously it was found that they were less common among unmarried women than in those joined in lawful wedlock. The explanation given is that there is obviously less scope for a girl-mother to cultivate fancies than in the case of young married women, whose word for the time being is law, and who are enabled, in virtue of superstitious tradition, to impose their whims on their friends; in other words, to take advantage of the situation and insist upon indulgences which would not reasonably be granted under other circumstances.

THE GENTLE TOUCH.

Mr. Bilton Pollard, in his address before the University College, London, gave a very timely and practical hint regarding the kindly treatment of hospital patients by internes. We regret to say that such a lesson is occasionally much needed in many of our public institutions, and the heeding of it will give that necessary exercise of the finer humanities which fits the graduates for the higher grades of successful practice among the so-called cultivated classes. The lecturer very properly maintains that an interne who can, by his gentle methods and appreciative sympathy, win the love and friendship of his poor and dependent patients, has gained as important an experience as any he can obtain in the hospital ward. Not that the ordinary hospital attendant intends any wrong, but there is, in some instances, a sudden inflation of his importance which invites dictatorial brusqueness, and an indisposition, in the exercise of duties supposed to be more important, to give time and thought to the exercise of the better elements of his manliness, by a compassionate consideration for the sufferings of such as are at his mercy. The cry of agony is never necessary for a diagnosis when the surgeon is the active agent of its production. The man who inflicts unnecessary pain in handling an injured limb is either a bungler or a brute.

The difference between the one who considers the feelings of his patient and the other who does not, is very apparent in the examination of a wound or the manipulation of a fracture. In the former the practised delicacy of touch discovers all that is necessary to know concerning the extent or character of the wound, without a sign of pain from the patient; while the latter, by the pressure and twist in the wrong place and at the wrong time, transforms the patient from a quiet, helpful, and submissive subject, to a shrieking and horrified sufferer. Even the most ignorant patient takes such lessons to heart. With a rich patron the question of choice could very easily be settled, but usually the sick or injured pauper must submit to the inevitable. When we consider that the highest science aims to mitigate pain, we can hardly claim superior accomplishments or greater depth of learning for the man whose very touch is signalized by a howl.

While it may not be possible for everyone to obtain this refinement of manipulation, there is no excuse for not cultivating it in every instance. Scientifically speaking, a sick beggar is the same as a sick king. Their nervous systems are made alike, their reflexes are similar, and their pain-centres are equally responsive. The one who can learn early to treat them from the same standpoint of appreciation becomes the sympathizing friend of both, and will be as welcome in the palace as in the hovel. There may be a reason why all cannot be great physicians, but we all can be gentle ones. Even in our most desperate cases, when all other remedies fail, the very last to lose its influence is the kind word fitly spoken.

MR. HART ON QUARANTINE.

Mr. Ernest Hart delivered an address before the Section on Public Health of the Academy of Medicine, last week. His topic was cholera and quarantine, and he presented forcibly the very familiar English views upon this subject. The English practice of discarding quarantine was adopted in 1866, and the Continental governments were gradually adopting it. Mr. Hart said that there had been no epidemic in the past fifty years which had not been due to quarantine. He cited in particular the last cholera epidemic in England, which killed six thousand people and laid hold of sixteen thousand more, and said the disease had been communicated to the people by a family which had passed quarantine and had polluted the water of the river Lee. He believed that an effectual quarantine would be caused alone by a Chinese wall. Quarantine was full of cruelties and commercial dangers, and it enlisted against it the commercial and chivalrous instincts of man. The moment that you made cholera contraband it would be smuggled in.

The English health authorities had a system of medical inspection which did not pretend to be exclusive. It confined itself to the sick, and did not inflict cruelties and indignities upon those who are not sick. That is to say, in cases of ships coming into port, only the sick would be held. This had a tendency to discourage the smuggling in of cholera, because it was for the interests of ship captains to own up and tell about the sick, knowing that those of the passengers who were well would not be held.

There was nothing as easy to keep out and deal with as cholera. The fear of cholera had saved more people than all the epidemics had destroyed and could destroy in fifty years. The knowledge that it is a disease due to dirty water, and to filth and uncleanliness, had compelled local authorities to take such measures as would prevent the disease. Since 1866, when the quarantine did not keep out cholera, there had been spent in the cities in England £22,000,000 in supplying pure water, and £12,000,000 had been expended on sewage works. Now they could snap their fingers at cholera.

The views thus enunciated are quite well known to American sanitarians, and we believe it to be the opinion here that we will eventually abolish quarantine in its

strictest sense. But the sanitary organization of the country is not yet perfect enough to allow it. Neither is the drainage and water-supply of our cities and towns sufficiently perfect to justify the inspection method followed by the English.

DOCTORS AND REPORTERS.

In a recent address on journalism, Mr. Charles A. Dana indicated certain qualities as desirable for the journalist, which we should say were also particularly necessary for a physician. Mr. Dana says: "There is no question that accuracy, the faculty of seeing a thing as it is, of knowing, for instance, that it is two and one-quarter and not two and three eighths, and saying so, that is one of the first and most precious ends of a good education. Next to that, I would put the ability to know how and where most promptly to look for what you don't know, and what you want to know. Thirdly, I would put Dr. Walker's great object, being able to tell what you know, and to tell it accurately, precisely, without exaggeration, without prejudice, the fact just as it is, whether it be a report of a baseball game, or of a sermon, or of a lecture on electricity, whatever it may be, to get the thing exactly as it is. The man who can do that is a very well-educated man."

It is this accuracy of observation which is particularly needed by medical men, and which their training ought to secure to them. We believe that to a large measure it does, and that physicians as a class are the most observant of people. The reporter, unhappily, is taught by the exigencies of competitive journalism to see, or at least to record, a little more than exists. He must have an interesting story, or the blue pencil goes through his copy.

News of the Week.

New York Cancer Hospital.—An examination for position of Junior Surgeon on the House Staff will be held at the New York Cancer Hospital, 106th Street and Eighth Avenue, on Wednesday, October 25, 1893, at 2.30 P.M. The term of service is twelve months; four as Junior Assistant, four as Senior Assistant, and four as House Surgeon. Application may be made to Dr. B. F. Curtis, 307 Madison Avenue, between 5 and 6 P.M. Fully seventy-five per cent. are major operations, and the experience in gynecology and general surgery is especially desirable; the number of surgical cases and operations comparing favorably with any large general hospital.

Pure Milk for Babies and Rules for Dairymen.—The Committee on Dairies, Section on Pediatrics, New York Academy of Medicine, reported as follows: "It having been conclusively demonstrated that a great and dangerous source of contamination of milk comes from dirt and filth from the cow's coat, bag, and udders, and from the milkmen's hands, it is especially requested by a committee appointed by the Pediatric Section of the New York Academy of Medicine that dairymen see that all visible dirt be removed from the cow's coat immediately before each milking, and that the bag and udders are cleansed at the time of milking, and that the milkmen wash their hands thoroughly with soap and water before milking. Antiseptic surgery has proven that absolute cleanliness is a preventive of germ contamination. Milk is a most fertile fluid for germs of all kinds when they have once gained access to it. By means of absolute cleanliness in the manner already indicated the most prolific source of disease from contaminated milk will be avoided. Again, it is an established fact that numerous epidemics of contagious diseases in cities and towns have originated from infected milk, such epidemics having been frequently traced to the milk. Infection of the milk in these cases is generally due to the milkman being in attendance on some patients with contagious disease at the time, or in his handling or cleaning cans or jars in which milk is to be transported, or from the sick themselves performing the same duties, either at the outset of an illness or during convalescence.

"Still another common source of infection is from washing the cans and jars in impure water. Creek water should be regarded as dangerous for the cleansing of vessels. It is therefore urged that only spring water or pure well water be used for washing all milk utensils. We urgently appeal to the dairymen to assist us in preventing this great source of disease and death from the one and only proper food of infants and young children. If farmers would put into practice these simple suggestions, they would soon drive from the market all 'infant foods' which are now so largely sold at enormous profits."

The Red Cross to the Front.—Washington, October 2d. Miss Clara Barton, President of the American National Red Cross, has officially accepted and assumed control of the relief of the sea island sufferers, tendered two weeks ago by the Governor and committees of South Carolina. This implies the housing, feeding, clothing, and nursing of thirty thousand people for eight months, with no aid from the Government and no fund but the direct charity of the American people. Her headquarters and address are at Beaufort, S. C.

The Death of Dr. Charles Slover Allen by Typhoid Fever.—Dr. Charles Slover Allen, aged thirty-eight years, died of typhoid fever at the Presbyterian Hospital, October 15th. He came to town from Larchmont on Friday morning, feeling feverish and sick. At noon on Saturday, at his request, he was taken to the Presbyterian Hospital. His fever increased, and in the afternoon of the next day he died. Dr. Allen was graduated from the Bellevue Medical College in 1881. He was a member of the University Club, Columbia College Alumni Association, Psi Upsilon, Manhattan Athletic and Larchmont Yacht Clubs, American Geographical Society, American Museum of Natural History, and the Metropolitan Museum of Art.

Expenses of the Hospitals.—At the recent meeting of the Saturday and Sunday Hospital Association it was shown that during the year the total expenses of maintaining the thirty-one hospitals under the Association's management had been $1,173,474.32. The thirty-one hospitals received 20,691 patients, of which number 15,417 were treated free, including 193,099 out-door patients. And yet the younger doctors complain of the hard times!

Discovery of the Typhus Bacillus.—A cable despatch announces the discovery of the typhus bacillus by Professor Fraenkel, of Berlin. He claims to have used it with success in immune experiments.

The Death of Dr. Elijah A. Maxwell.—The Medical Board of Randall's Island Hospital hear with great sorrow of the death of their associate, Dr. Elijah A. Maxwell. He was for many years a member of this Board, of affable and pleasant manners he was a warm friend and wise counsellor. Therefore be it

Resolved, That in his untimely death we have lost our most beloved associate and a break is made in our number which cannot be filled. His memory will ever remain among the most pleasant of our lives, and will inspire us with an ideal of professional and manly excellence toward which it would be well for us to shape our future lives.

Resolved, That the loss we mourn is not limited to this Board but is shared by the medical profession as a whole.

Resolved, That to his family we tender our warmest sympathy; and be it also

Resolved, That a copy of these resolutions be sent to his family, a copy entered in the minutes of the Medical Board, and also a copy sent to the medical press.

EDWARD WAITZFELDER, M.D.,
WALDRON D. VANDERPOEL, M.D.,
Committee of the Medical Board.

Death of Dr. Edwin T. Doubleday.—At the last stated meeting of the New York Hospital Alumni Association, April 28, 1893, the following preamble and resolutions were authorized:

Whereas, It has pleased the Almighty Father, in his omnipotent wisdom, to remove from us Dr. Edwin T. Doubleday, a past House Officer of the New York Hospital, an original member of this Association, and its Secretary since its inception; and

Whereas, Dr. Doubleday was, throughout his professional career, a devoted student and an accomplished practitioner, both in the hospital and in his private work; and

Whereas, He was a gentleman who by his kindly nature and his thoughtful interest in others endeared himself to all with whom he came in contact; Therefore be it

Resolved, That we, the members of this Association, do hereby express our deep grief at his untimely death, and our sense of personal loss. And be it further

Resolved, That we tender to his bereaved family our profound sympathy in this their affliction. And be it further

Resolved, That a copy of the foregoing be presented to the family of the deceased, and that it be sent to the medical journals of this city.

CHARLES A. POWERS, M.D.,
GEORGE A. RICHARDS, M.D.,
GEORGE H. COBB, M.D.,
Committee.

Dr. Jesse Lee Morrill, who has been ill with septicæmia, is slowly recovering.

L. Harrison Mettler, M.D., of Chicago, writes, concerning his article on seminal incontinence, that the dose of atropia should be from $\frac{1}{200}$ to $\frac{1}{100}$ of a grain.

The Study of Contagious Diseases.—It is stated that a proposition has been made to the New York City Board of Health to confer upon a staff of three or four physicians the privilege of visiting the hospitals of the Health Department, and so far as may be possible without interfering with the patients, of studying the various contagious diseases.

A Brainy Therapeutist.—A native of Georgetown, Md., has the following sign on the front of his store: "Born with brain within brain i can kure enny kind of misery in a short time with only the best erbs to be used."

The Yellow Fever at Brunswick.—There has been an unusually light rate of mortality in the Brunswick epidemic of yellow fever, which has existed for the past five weeks, and has not yet given any sign of abatement. The rate at other places often ranges from ten to forty or fifty per cent., and has at times gone even beyond fifty; but an examination of the figures from Brunswick, since an early date in September, show that on the average it has not risen above seven or eight per cent. there this year. In the last week of September it was as high as twelve; in the first week of October it was as low as eight, and latterly it has fallen still lower. About five hundred persons have so far been attacked.

The Third Annual Report of the State Board of Medical Examiners of New Jersey.—During the fiscal year now ended there have been examined one hundred and fifty applicants, and one hundred and fifteen certificates have been issued to practise medicine in that State; also eleven certificates in the primary branches, which, while they do not entitle the holders to practise medicine, yet exempt them from examinations in these branches when they take their final examination one year thereafter; of the remaining twenty-four, four withdrew before completing their examinations, giving only thirteen and one-third per cent. of rejections as compared with nearly eighteen per cent. in 1892, and nearly sixteen per cent. in 1891, thus showing very prominently that the candidates have been prepared for their work by their respective colleges with much greater care and thoroughness than in former years. The Board states that its examinations during this year have been even harder than in 1891 and 1892, so that it can very justly claim that it has even in so short a time very materially elevated the standard of the medical profession, at least of the new-comers, in that State, thereby not only benefiting the profession of the State, but the great mass of the people thereof, and that, too, without taking a dollar from the State Treasury, except for the printing of these annual reports. The fees received from candidates, after paying stationery bills, printing, engraving, and mailing certificates, printing laws, rules and regulations, and furnishing examination paper, etc., scarcely pay the travelling expenses of the Board, not to mention the loss sustained in private business during its attendance upon the meetings of the Board; so, too, with the candidates, they are obliged to stay two nights and two days in Trenton, and if rejected, a repetition, besides paying the examination fee and travelling expenses, amounting in all to forty or fifty dollars. Hence the Board recommends that the State pay the examiners a fair salary and then have all the examinations free. That the law acts rather by exclusion than by rejection is proven by the fact that during our three years of existence we have examined only three hundred and ninety-seven candi-

dates, including the preliminaries and those previously rejected, and issued only three hundred and seven certificates to practise medicine, which only equals the number registered each year under the old law.

Typhoid Fever is epidemic in Berlin.

Malakin is the latest addition to the list of antiseptics, antipyretics, and antineuralgics. It is a derivative of salicylic acid and phenacetin.

The Digitalis Treatment of Pneumonia is unsafe and ineffective, according to Dr. Sieg. Reiner, of Vienna.

Tuberculin.—Dr. Thörner, of Berlin, has recently urged again the utility of tuberculin in tuberculosis.

Subgullate of Bismuth in ten-grain doses is said to be useful in chronic diarrhœa and fermentative dyspepsia.

Mika's Operation.—The *Lyon Médical* for September 24th contains an excerpt from *La Médecine Moderne* on a bizarre surgical operation that is practised by the aboriginal Australians. It consists in opening the inferior portion of the urethral canal near the scrotum. The wound is kept open until cicatrization produces a fistula. The operation is performed for the purpose of permitting of coitus and insuring relative sterility. In one Australian tribe M. Mikuho-Maclaya has counted three hundred men so operated on, while only three or four had the urethræ intact. These latter males were the most magnificent specimens of the race. M. Gazorowski recalls the fact that the aborigines of Santo Domingo practised a similar operation on horses in the eighteenth century, so as to preserve all their vigor without the power of procreation. Sterility so produced is evidently only relative, for sperm deposited at the entrance of the vagina sometimes suffices to fecundate.—*New York Medical Journal.*

Italian Surgeons seem able to acquire fortunes and at the same time philanthropy. The late Professor Pacchiotti recently bequeathed a large sum to the University of Turin; and the late Professor Olivieri, of Naples, has bequeathed $100,000 to two of the hospitals of that city.

Stanley's Tribute to Surgeon-Major Parke.—"Himself depleted in body from excessive perspiration after a march through hot, moist jungles, starving on one green banana a day, half-naked from loss of clothing and the constant wear and tear of bush life, half-fainting from the pernicious ague, which could only be suppressed by heroic doses of quinine, and yet presenting to each and all of us a face whereon one read naught but pleasantness and benevolence. Pursuing steadily, day by day, throughout a period which has no equal in my life for downright utter and extreme misery, an even temper so admirable and beautiful for its sweetness and devotion, that I can think no human being, male or female, could excel it. It is here, in the possession of these natural gifts, this charming benignity, that I think Parke is great. Oh! at such a time had the ordinary human creature stood up and freed the pent-up feelings with a shout of blasphemy and explosive fury, we could not have remembered it as a sin against poor, weak, over-pressed human nature; but never within my hearing or knowledge did I hear a murmur or a mean expression. That singular sweetness and tender anxiousness, having been noted by me so often when he sat in the midst of his patients unsuspecting, remain stamped on my mental image of Parke, and calling him now up to my mind I can see nothing else but that. The 'Doctori,' as the Zanzibaris called him, was to them a friend to whom they might expose their constant and ever-recurring ailments, for no one but one who was sincerely friendly could look as he did, or speak so soothingly and comfortingly."

Opening of the Johns Hopkins Medical School.—The regular courses leading to an M.D. degree at the Medical School of Johns Hopkins University opened on October 5th with a class of sixteen, of whom three are women. The high standard set by Johns Hopkins for admission to this school has, for the first time in the United States, secured a band of medical students each with a bachelor's degree from some reputable college. Of the thirteen men, Johns Hopkins supplies four; Yale, three; Harvard, two; and Amherst, Swarthmore, Virginia Agricultural College, and the University of Wisconsin, each one. The women are graduates respectively from Smith, Vassar, and Wellesley.

The Abuse of Medical Charities.—The British Medical Association has inaugurated a determined fight against the abuse of medical charities in Great Britain, and as a means to that end its committee recommends (1) that a wage-limit be established, above which income persons applying for treatment will be required to pay fees; and (2) that the hospitals and dispensaries hereafter have displayed in a conspicuous place within their precincts a placard bearing the following inscription: "This institution being established to relieve only those persons who are too poor to pay for suitable medical aid, notice is hereby given that on and after this date patients will be required to give information as to their means and circumstances, with a view to prevent the abuse of this charity by persons who are well able to pay." Cannot American hospital authorities be moved to "go and do likewise?"—*Medical News.*

The Census of the Medical Profession of Great Britain makes the total number of members of the medical profession 85,235. But of these, 30,843 are males, 54,392 females, the latter including midwives and nurses! The English census thus puts nurses in the medical profession; the London directories class physicians among the tradesmen!

Extreme Anti-adulteration.—There is an old story of some man who studied the subject of the adulteration of various popular articles of diet until he grew so impressed by the dangers attendant on food that he gradually gave up one thing after the other, eventually dying of want of nourishment. We may hope to avoid his fate, but still our indulgences are being daily restricted. We have to submit to boiled milk, which is no great hardship, and to boiled water, which is certainly nasty, and yet we know it to be wholesome, and so we dare not rebel. In their zeal against harmful things, some people would prohibit good as well as bad fruit, entirely forgetting that in food as well as drink temperance means moderation, not necessarily "total abstinence." But the latest dictum, that we must not clean our teeth with ordinary filtered water unless it is also boiled, is surely converting common-sense precautions into the similitude of absurdities.

Society Reports.

NEW YORK STATE MEDICAL ASSOCIATION.

Annual Meeting, Held in Mott Memorial Hall, New York City, October 9 to 12, 1893.

S. B. WYLIE MCLEOD, M.D., PRESIDENT, IN THE CHAIR.

FIRST DAY, MONDAY, OCTOBER 9TH—EVENING SESSION.

Address of Welcome.—DR. JOHN G. TRUAX, of New York, Chairman of the Committee of Arrangements, read a brief address of welcome, outlining the proposed work of the Association at this meeting, laying some stress upon the importance of the social features, and making touching allusion to one of the most devoted members, then on his death-bed, Dr. Alfred L. Carroll.

The President's Address.—DR. MCLEOD'S address consisted in an epitome of the addresses of the several presidents during the first decade of the Association's existence, and of the papers upon ophthalmology, materia medica, and insanity read during the same period. An analysis of papers upon surgery, obstetrics, etc., would be presented by other writers whose names appeared upon the programme.

The presidential addresses had been by Drs. Didama, Detmold, Moore, Taylor, Cronyn, Lusk, Orton, Stephen Smith, Andrews. They had been upon ethics, or the relations of members of the profession to one another, and those existing between the profession and the public; upon medical education, medical progress for the year, and upon special scientific subjects. The President thought this epitome showed that the Association had done much and superior work during its brief existence. The entire number of papers and dissertations had been 476, of which 181 had been on surgery; 151 on medicine; 72 on obstetrics and gynecology; 24 on pathology; 15 on materia medica; 10 on insanity; 8 on ophthalmology; 6 on state medicine; 4 on hygiene; 2 on physiology; 1 on toxicology.

The membership had increased to 800. The number of volumes in the library was 9,045.

"Now, fellows of the Association, let us close our books on the termination of the first decade, and open others for the commencement of the second. We have encouragement, we are prosperous; let us from this time on strive for greater and greater success."
